INTRODUCTION.

THE value of science is best shown by its influence on the happiness and well-being of mankind. This is a truism which cannot be too often borne in mind by those who impart as well as by those who receive scientific instruction. It is a constant reference to this fact which so much enhances the real importance of our modern books of science over those of the ancient schoolmen. Deep metaphysical researches, frequently combined with an ingenious play on words, formed the prominent features in their ponderous folios; and the labour of a life-time was frequently productive of less real benefit to mankind than is now effected by the sale of a single unassuming tract really fitted to impart information. Costly domes and monkish establishments were also at one period considered as the only fanes worthy of disseminating the dogmas of scholastic science; but now its study is pursued in temples of another and far more ennobling kind. Temples dedicated to the worship of the Living God have not been considered as desecrated by being appropriated to the task of teaching man how to think rationally, as well as how to adore that great and good Being who has furnished such abundant materials for the delight and improvement of his creatures. In the course of this Introduction we purpose enquiring what are the species of scientific knowledge to which the humblest may aspire, and beyond which even the most wealthy rarely receive any essential advantage.

The structure of the universe, an acquaintance with the motions and general mechanism of the heavenly bodies, are subjects within the ken and may be rendered intelligible to the meanest capacities. The structure of the human body also, as well as its general functions, may readily be made the source of much delightful as well as profitable investigation. By combining a knowledge of optics with this branch of study, we are enabled to illustrate experimentally that most extraordinary of all natural structures—the human eye, and to show how, by the agency of certain crystalline bodies differing in their refractive power, an optical instrument may be formed which far exceeds in perfection all that the sages of ancient Greece or Rome bodied forth in optical science. This one instance may suffice to point out how important it is for the student to combine the study of nature's volume with that of the laborious deductions from experimental investigation.

Mechanical science offers at first view but few attractions to the student, and it certainly does not abound in the same moral lessons which may be acquired by a careful study of natural history; but even here a wide field of interesting investigation opens itself to the enquiring mind. He finds by a careful comparison of his most perfect mechanical agents with the frame-work of "nature's master-piece, man," that they are but clumsy attempts to

imitate the every-day work of a Being who has surrounded us with examples of his own perfection, compared with which our most ingenious inventions and highest wisdom are but foolishness.

Even the mere historical enquirer may derive considerable advantage from this branch of study, as he may thus be enabled to point out the processes by which the various gigantic monuments of early superstition were erected, and to trace the history of edifices, and to fix a date for their erection, by simply referring to the mechanism of their construction.

The changes observable throughout nature result either from the mutual actions of the minute particles of bodies exerted at imperceptible distances, and producing a permanent alteration in their constitution, or from the action of separate masses, exerted at sensible distances, and producing alterations in their relative positions. In the first case, the phenomena belong to that department of experimental philosophy which is denominated chemistry. The study of the phenomena exhibited in the latter case constitutes natural philosophy, or rather that department of experimental science to which the term physics is applied.

Thus we see that the provinces of the chemist and natural philosopher are distinct. Whilst the business of the former is to ascertain and classify the primary elements of bodies, and to trace the effects and comparative degrees of agency of the forces exerted among the minute particles of matter, which are incessantly and insensibly producing permanent changes in the constitution of these bodies, that of the latter is to classify the effects and measure the intensity of those forces which are continually tending to produce changes in the relative positions of bodies as they exist in nature, without at all effecting any change in their constitution, and hence to explain the phenomena which result from different combinations and modifications of these forces. In many cases, indeed, the same force may come within the province of each. Heat, for instance, is the object of the chemist's consideration, in as far as it is efficacious in changing the character of various substances, or in resolving compound bodies into their component elements, and uniting elementary substances into distinct compound bodies; but it also comes within the cognizance of the natural philosopher, in as far as it is the cause of alterations in the dimensions of homogeneous bodies that may be subjected to accurate measurement or calculation.

The importance of keeping steadily in view the connection between the physical sciences may be best illustrated by comparing the ancient and modern systems of astronomy; for it was the study of terrestrial mechanics that first led to the discovery of the mechanism of the universe. And the reason why the ancient theories of astronomy were so fanciful and absurd is, that ancient philosophers went to investigate what was distant, before they made themselves acquainted with what is near, and tried to know the heavens while utterly ignorant of the earth. To show the hazard of investigating one science independently of another, we shall quote the words of Mrs. Somerville, who has written a valuable work on this subject.

"The theory of dynamics, founded upon terrestrial phenomena, is indispensable for acquiring a knowledge of the revolutions of the celestial bodies and their reciprocal influences. The motions of the satellites are affected by the forms of their primaries, and the figures of the planets themselves depend upon their rotations. The symmetry of their internal structure proves the stability of these rotatory motions, and the immutability of the length of the day, which furnishes an invariable standard of time; and the actual size of the terrestrial spheroid affords the means of ascertaining the dimensions of the solar system, and provides an invariable foundation for a system of weights and measures. The mutual attraction of the celestial bodies disturbs the fluids at their surfaces, whence the theory of the tides and the oscillations of the atmosphere. The density and elasticity of the air, varying

with every alternation of temperature, lead to the consideration of barometrical changes, the measurement of heights, and capillary attraction; and the doctrine of sound, including the theory of music, is to be referred to the small undulations of the aërial medium. A knowledge of the action of matter upon light is requisite for tracing the curved path of its rays through the atmosphere, by which the true places of distant objects are determined, whether in the heavens or upon the earth. By this we learn the properties and nature of the sunbeam, the mode of its propagation through the ethereal fluid, or in the interior of material bodies, and the origin of colour. By the eclipses of Jupiter's satellites, the velocity of light is ascertained, and that velocity, in the aberration of the fixed stars, furnishes the only direct proof of the real motion of the earth. The effects of the invisible rays of light are immediately connected with chemical action; and heat, forming a part of the solar ray, so essential to animated and inanimated existence, whether considered as invisible light or as a distinct quality, is too important an agent in the economy of the creation not to hold a principal place in the order of physical science, whence follows its distribution over the surface of the globe, its power on the geological convolutions of our planet, its influence on the atmosphere and on climate, and its effects on vegetable and animal life, evinced by the localities of organized beings on the earth, in the waters, and in the air. The connection of heat with the electrical phenomena, and the electricity of the atmosphere, together with all its energetic effects, its identity with magnetism, and the phenomena of terrestrial polarity, can only be understood from the theories of these invisible agents, and are probably principal causes of chemical affinities. Innumerable instances might be given in illustration of the immediate connection of the physical sciences, most of which are united more closely by the common bond of analysis, which is daily extending its empire, and will ultimately embrace almost every subject in nature in its formulæ."

Expensive apparatus was formerly considered as essential to the study of science in any useful or tangible form; this however is as erroneous as it is to suppose that highly aristocratic establishments are essential to a well-grounded acquaintance with the principles of mathematical study. Who is there who has not heard of the unassisted labours of James Ferguson the shepherd boy? For him the figured volume of a Euclid, and the laborious investigation of a Newton, had appeared in vain, and he carved out a path of study for himself, unaided by any other light than that of his own powerful mind. His apparatus consisted of a few beads and a piece of thread; and with these he marked the relative positions of the heavenly bodies, and was enabled to show with tolerable accuracy the degrees of velocity with which they moved through space.

The useless profusion and complexity of apparatus formerly considered essential for experimental chemistry was a great obstacle to the advancement of this science in the last and preceding centuries; and it was only in the ducal palace of Magdeburg, and in the laboratories of our own Royal Society, that they were pursued with any success. Chemical apparatus was first simplified by the celebrated Priestley, who showed that a few glass tubes and a Florence flask were all that was essential to discoveries of the greatest magnitude.

We may now however proceed to trace in detail the progress of some of the most important branches of science, commencing with the employment of those simple mechanical appliances which, on account of their general utility, must have evidently earliest engaged the attention of mankind. To render our view, however, intelligible to the reader, we must first examine the nature of attraction, and trace our acquaintance with that invisible yet all-pervading energy, which acts alike on the vast frame of creation, guiding the planetary orbs in their course through space, and giving a form and character to the minutest drop of dew.

The great principle of attraction, in the Newtonian sense of it, seems to have been first examined by Copernicus. "As for gravity," says this distinguished philosopher, "I consider it

as nothing more than a certain natural appetence that the Creator has impressed upon all the parts of matter, in order to their uniting or coalescing into a globular form, for their better preservation; and it is credible that the same power is also inherent in the sun, and moon, and planets, that those bodies may constantly retain that round figure in which we behold them." Kepler calls gravity a mutual and corporeal affection between similar bodies, acting so as to produce their union; and he afterwards more positively asserts that no bodies whatever were absolutely light, but only relatively so, and consequently that all matter was subject to gravitation. Lord Bacon and Dr. Gilbert come next in order, though they added but little to our knowledge on the subject; and we must look to Newton for the first correct notions in connection with gravitation. The ancient attraction was supposed to be a kind of quality inherent in certain bodies themselves, and arising from their particular or specific forms. The Newtonian attraction is a more indefinite principle, and he states that he uses the words attraction, impulse, and propulsion to the centre, indifferently; and cautions the reader not to imagine that by attraction he expresses the modus of the action, or the efficient cause thereof, as if there were any proper powers in the centres, which in reality are only mathematical points; or as if centres could attract. So that he considers centripetal powers as attractions, though, physically speaking, it were perhaps more just to call them impulses, and he concludes by observing that what he calls attraction "may possibly be effected by impulse, though not a common or corporeal impulse, or after some other manner unknown to us. Attraction, if considered as a quality arising from the specific forms of bodies, ought therefore, with the whole list of absurd occult qualities, to be exploded. But, when we have set these aside, there will remain innumerable phenomena of nature, and particularly the gravity or weight of bodies, or their tendency to a centre, which argue a principle of action seemingly distinct from impulse, where at least there is no sensible impulsion concerned. Nay, what is more, this action in some respects differs from all impulsion we know of, impulse being always found to act in proportion to the surfaces of bodies, whereas gravity acts according to their mass, and consequently must arise from some cause that penetrates or pervades the whole substance of the body. This unknown principle—unknown, we mean, in respect of its cause, for its phenomena and effects are most obvious—with all the species and modifications thereof, we call *attraction*, which is a general name under which all mutual tendencies, where no physical impulse appears, and which cannot therefore be accounted for from any known laws of nature, may be ranged."

Attraction may be divided, with respect to the law it observes, into two kinds. Firstly, that which extends to a sensible distance. Such are the attraction of gravity, found in all bodies; and the attraction of magnetism and electricity, found in particular bodies. For an account of the laws and phenomena of each, see their respective articles in this cyclopædia.

The attraction of gravity, called also among mathematicians the *centripetal force*, is one of the greatest and most universal principles in all nature. We see and feel it operate upon bodies near the earth, and find by observation that the same power operates on the other planets, primary as well as secondary; and even that this is the very power by which they are all retained in their orbits, &c. And hence, as gravity is found in all the bodies that come under our observation, it is easily inferred, by one of the settled rules of philosophising, that it obtains in all others; and, as it is found to be as the quantity of matter in each body, it must be inherent in every particle, and hence every particle in nature is proved to attract every other particle.

From attraction then arises all the motion, and consequently all the mutation, in the physical world. By this heavy bodies descend, and light ones ascend; by this projectiles are directed, vapours and exhalations rise, and rains, &c., fall. By this rivers glide, the air presses, and the ocean swells, in obedience to the laws which regulate the tides.

We may now notice that species of attraction which does not extend to sensible distances. Such is found to obtain in the minute particles whereof bodies are composed, and which attract each other at or extremely near the point of contact, with a force much superior to that of gravity, but which at any distance from it decreases much faster than the power of gravity. This is termed the *attraction of cohesion*, as being that by which the atoms or insensible particles of bodies are united into sensible masses.

This latter kind of attraction owns Sir Isaac Newton for its discoverer, as the former does for its improver. But, besides the common laws of sensible masses, the minute parts they are composed of are found subject to some others, which are thus illustrated by Newton :—" In virtue of these powers," he says, " the small particles act on one another even at a distance; and many of the phenomena of nature are the result thereof. Sensible bodies act on one another in divers ways; and we thus perceive the tenour and course of nature. It appears highly probable that there may be other powers of the like kind; nature being very uniform and consistent with herself. Those just mentioned reach to sensible distances, and so have been observed by vulgar eyes; but there may be others which reach to such small distances as have hitherto escaped observation; and it is probable electricity may reach to such distances even without being excited by friction."

These phenomena, " in virtue whereof the particles of the bodies above mentioned tend towards each other," Newton calls by a general indefinite name *attraction*, which is equally applicable to all actions by which distant bodies tend towards one another, whether by impulse or by any other latent power; and from hence he accounts for an infinitude of phenomena, otherwise inexplicable, to which the principle of gravity is inadequate. " Thus," adds our author, " will nature be found very conformable to herself and very simple, performing all the great motions of the heavenly bodies by the attraction of gravity, which pervades those bodies, and almost all the small ones of their parts, by some other attractive power diffused through the particles thereof. Without such principles, there never would have been any motion in the world; and without the continuance thereof motion would soon perish, there being otherwise a great decrease or diminution thereof, which is only supplied by these active principles."

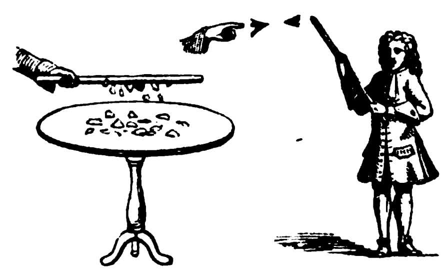
The attraction which subsists between the particles of fluid bodies was first investigated by the Academy del Cimento. But the completest series of experiments on capillary action was made by our countryman Hauksbee. He proved that it is not affected by atmospheric pressure, and succeeds equally well in *vacuo;* he showed the ascent of water and other liquids between proximate glass plates, and compared it with the rise in narrow tubes; and he ascertained the elevation to be always inversely as the width of the bore or the separation of the plates. He found that the same property belongs to marble and brass, and remarked the ascent of water in an open barometer tube filled with fine ashes. Dr. Brooke Taylor likewise performed several ingenious experiments on this subject: having joined two plates of glass at their vertical sides so as to form a sharp wedge, he dipped it in a vessel of water, and observed the liquid to rise and form a rectangular hyperbola, thus clearly exhibiting the relation of the ascent to the interval between the proximate surfaces. But he pursued the phenomena of corpuscular attraction still further, and measured the adhesion of a disk of glass to water and mercury. Seventy years afterwards this enquiry was resumed by the celebrated Guyton Morveau, who endeavoured to ground upon it the chemical theory of elective attraction. The attempt however was fallacious, because the force required to detach a disk of glass, marble, or metal, from a surface of water or mercury, is not a single effort, but combines the adhesion of the liquid particles to the solid with their cohesion to each other. In 1718, Dr. Jurin, being led to examine the phenomena of capillary attraction, proposed a theory for their explication which seemed at least plausible. He

rightly ascribed the rise of water in the cavity of the tube to the close attraction of the internal surface of the glass, though he did not perceive the way in which that force must act. He fancied the suspension of the slender column of liquid to be caused by the attraction of the ring of glass immediately *above* its summit. But such an assumption was quite illusory; for the ring *below* that limit would evidently exert an equal force in the opposite direction, and thus extinguish the influence of the former.

It is, however, to Segner that we are indebted for the first accurate view of the theory of capillary attraction. He took up the subject in 1754, and gave a different solution, distinguished by its depth, ingenuity, and general accuracy. Assuming as a principle that the attractive energy is confined to a mere exterior film of the liquid, he found the curve of the upper surface to be what is called the *Lintearia*, or the cavity of an inflated sail formed by a uniform tension. The results he obtained were perfectly accordant with the phenomena, except in the figure of a drop of water, in the determination of which he had, from overlooking the double curvature, committed a small error.

Nearly half a century more elapsed before any further attempt deserving notice was made to improve the theory of capillary attraction. In 1804, the late lamented Dr. Thomas Young resumed the investigation of this subject, and obtained a very complete solution, but which required the admission of a repulsive force among the particles of the liquid at a certain small distance. These investigations were subsequently resumed bv Mr. Ivory, who threw considerable light on the subject of capillary attraction.

The attraction which results from a disturbance in the electrical equilibrium may next be adverted to. There were some very ridiculous doctrines taught by the ancient schoolmen in connection with this species of attractive energy. They believed that there were sympathies between different bodies which caused them to attract others and elicit light when they were excited by friction. The whole train, however, of these absurdities have been swept away by the discoveries of Franklin, Davy, and Faraday. The apparatus employed by the early experimentalists in this branch of science, though very inefficient, was yet sufficiently simple. Mr. Grey, who was resident in the Charter House early in the last century, was an ingenious electrical philosopher. He is represented with his apparatus in the subjoined sketch. He was enabled to raise light pieces of paper by exciting a glass tube, and his apartments became the resort and wonderment



of the little knot of philosophers who flourished at the period, and whose proceedings were carefully chronicled by several members of the Royal Society.

This ingenious philosopher was also enabled to give a spark to the finger when presented to the tube, as is shown in the other portion of the figure. When Mr. Grey wished to increase the power of his apparatus, he went out into his balcony, and then, by the agency of a long piece of wire suspended by a silk thread, he obtained a sufficient conducting surface for his purpose. We cannot in the present place pause to compare this pigmy and ill-assorted apparatus with the giant machines employed in the Teylerian Museum, which melted bars of metal, burnt combustible bodies, illuminated the apartment, and indeed exhibited all the terrific phenomena of the very bolts of heaven. But it is a curious and interesting task to trace these incipient efforts of philosophy in her infancy, as a little more glass and metal, aided by a little more experience, would have converted Mr. Grey's apparatus into one fitted for the lecture-table in the present day.

Strictly speaking, the science of mechanics includes the laws of matter, motion, and force.

The first of these possesses the attributes of solidity and inertiæ; it is divisible as far as our senses or even our imagination can go, but we are certain that its ultimate particles must be indivisible, or at least that they are never divided in the operations of nature. In the proper sense of the term, no matter is solid; for no mass is destitute of pores into which other substances may not be introduced. Thus wood contains air between its fibres, and air contains water diffused in it in the state of vapour. With reference to the actual solidity of the particles of which firm bodies are composed, it appears certain that they act on each other without really being in contact, by means of powers connected with them, put in operation by the Author of all things. Where the forces act with great intensity, the body presents the quality of hardness, resisting any attempt to separate the particles: where their sphere of action is of some extent, it is termed elastic, and possesses the power of resuming its original dimensions, when the power which compressed or extended it ceases to act. If the repulsive force be diminished, or the cohesive increased, the bulk of the body must diminish, as when it is compressed by an external force, or when its temperature is reduced. That being always an antagonist to cohesion, by its action solids become fluid, and liquids are changed into vapours, the intermediate steps being marked and measured by their expansion.

Inertia is a term invented to express that quality of matter by which it is indifferent as to rest or motion, that passiveness to every impulse which is so decidedly its attribute. Were there no other being in the universe it must be for ever unmoved and dead; were it once put in motion it must move for ever: and they who dreamed that the universe was caused by a fortuitous concourse of atoms showed their absolute want of observation. That matter has no power to put itself in motion every one will readily admit; but it is thought by some difficult to conceive how it can be indifferent to rest. At the first view it appears that all motions decay, and that, as some cause is required for their beginning, so it is necessary to maintain them; but, if we examine more minutely, we find that there exist around us phenomena capable of producing this loss of motion, and to which therefore it must be attributed, such as the resistance of the air, friction, stiffness of cordage, &c. If these be diminished (for they can never be removed), the motion is prolonged, and to such a degree as decidedly shows that if they were entirely removed the motion would be perpetual. The quality of absolute inertia belongs only to matter in the abstract; for every atom of it with which we are acquainted acts on others, being the vehicle of the energies by which the Governor of the universe has ordered his works to be swayed.

We have seen that gravitation resides in every particle of the solar system; electricity, magnetism, and heat, are in this globe almost omnipresent; and the actions of bodies on light, and the play of chemical affinities, indicate the existence of countless forces resident in matter. But the effects of these are obviously distinct from the formation of matter itself, and cannot be explained by any material agency: besides, we see that they cannot affect our conclusions, for in our enquiries we are aware of their influence, and allow for it, considering them as unconnected with matter; as instances, we reason as if rocks were inflexible, cords pliable, and machinery void of weight, but merely conveyers of forces, and we obtain conclusions, true only in the abstract, but capable of being corrected for particular circumstances.

The sources of motion with which we are acquainted are, the energy of animated beings, the forces to which we have already alluded as implanted in matter, and the impulsion of a body which communicates its motion to another, this last being scarcely entitled to the name of force.

Where one body communicates force to another, the quantities of motion lost and gained are equal, and they are measured by the quantities of matter multiplied into the velocities; thus, if the striking body be doubled, its quantity of motion must be doubled, and if its velocity also be doubled its motion is fourfold; and in the same way when a disturbing force

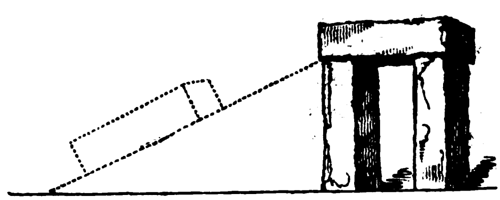
generates motion its energy is as the product of the mass moved into the velocity produced. The strength of animals is more manageable than most other movers; but the employment of it is narrowed by the limited velocity which they can produce, and by the variable nature of their exertions; and it is too often attended with circumstances revolting to humanity.

The most powerful forces which man has subjected to his industry are those of gravitation and expansion. A mass of solid matter descending from a height, a stream of water, and a current of air, afford potent movers, which are made useful by means of machinery. Still more energetic are the forces causing expansion; and the elastic force of steam, and the yet more formidable agency of gunpowder, give the means of exciting almost unlimited velocity. To devise the means of applying these to use in the most advantageous manner is the object of practical mechanics, and for the perfection of this art both theory and experiment must lend their aid, as it is equally absurd to despise the investigations of the analyst without understanding them, and to found elaborate researches on false data.

Now the mechanical powers, as they are called, are usually employed to counteract the effects of gravitation, and to produce effects which the unassisted powers of man could not otherwise accomplish; and it is astonishing how small is the change which time has effected in their arrangement. It is true that amazing advantages have been effected by their combination, but the elementary instruments were as well understood by Archimedes as by the philosophers of the present day.

Without such instruments it would rarely be possible to use any force except human strength, and the employment even of this would be very limited. In the least complicated of all mechanical efforts, that of raising a large weight as soon as it exceeded the strength of one labourer, a great difficulty would be experienced; and the average force of each individual would be proportionably less as their number increased. If, however, one man, by the aid of any mechanical instrument, can act against a force equal to tenfold his ordinary strength, and at the same time it be easy to combine the efforts of many with undiminished effect, there can be no limits to the tasks which they may perform. No force is generated in machines. All that is effected by them is to move a light body with speed, or a great weight slowly; and therefore they who have sought for a perpetual motion by the aid of machinery have but displayed their ignorance of the first elements of mechanics.

The implements employed by the early mechanics were usually of the most simple character; a bar of wood, or a mound of earth, appears to have served for the elevation of large stones that even in the present day would seem to require much more complicated apparatus. In our own island, even after the invasion of the Roman power, when the arts and civilization of the conquerors of the world might have taught the aboriginal inhabitants the use of mechanical inventions, we still find them in the most lamentable state of ignorance. The vast horizontal stones which still form part of the Druidical circle at Stonehenge have evidently been raised by the agency of an inclined plane of earth; but, as this subject has excited much controversy amongst antiquaries, we had better illustrate the matter by a diagram.



If we suppose the perpendicular stones to be erected, as shown in the figure, a mound of earth, forming an inclined plane, will readily suffice for placing the horizontal stone in its proper situation. The earthen plane may afterwards be removed, and thus all trace of the original process destroyed. By an arrangement of this kind, the celebrated traveller Belzoni was enabled to remove masses of stone which would otherwise have defied his utmost exertions. It must still, however, be borne in mind that a much greater

loss of power from friction results from the use of these primeval machines than when the improved implements of science are resorted to. In ancient times, whole nations of slaves were employed to raise pyramids and erect monuments, by which their energies were wasted and their lives ultimately destroyed, merely to gratify the caprice of a successful invader; while at the present period we are enabled to effect much greater works by the agency of machinery, and that too almost unassisted by human labour. An ingenious foreigner has published an estimate of the mechanical force set in action by the steam-engines of this country. He supposes that the *great pyramid* of Egypt required for its erection the labour of more than 100,000 men for twenty years; but that if it were required again to raise the stones from the quarries, and place them at their present height, the action of the steam-engines of England, which are managed at most by 36,000 men, would be sufficient to produce the same effect in eighteen hours.

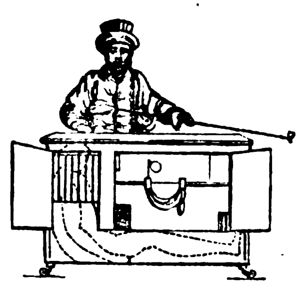
A good notion of the ordinary pursuits of the early mechanicians may be derived from their singular predilection for the construction of automata. The labour of a life-time was frequently devoted to the construction of a single figure. Among the ancients, Dædalus was famed for constructing machines that imitated the motions of the human body. Certain statues of his, it is said, had the power of moving about, and would run away unless forcibly detained. Aristotle speaks of these in his treatise *De Anima*, and affirms that the effect was produced by concealed quicksilver. This, however, could not be the case, unless the automata moved on a descending plane, like the Chinese toy called a tumbling mandarin, which, by means of mercury contained in the cavity of its body, is made to descend a series of steps. Friar Bacon and Albertus Magnus both exercised their ingenuity in the construction of androides, which appeared so wonderful to the ignorant multitude as to draw upon their inventors the dangerous imputation of being addicted to magic. Bacon is said to have constructed a brazen image capable of speaking; and Albertus Magnus formed an artificial man, in the construction of which he spent thirty years of his life. This, we are told, was broken to pieces by Aquinas, who came to see it, purposely, that he might boast how in one minute he had rendered fruitless the labour of so many years.

But these singular mechanical contrivances have also engaged the attention of many modern mechanics. Vaucanson invented some which are thus described by Beckman:—"One of them, which represented a flute-player sitting, performed twelve tunes, and, as we are assured, by wind issuing from its mouth into a German flute, the holes of which it opened and shut with its fingers. The second was a standing figure, which in like manner played on the provençal shepherd's pipe, which it held in its left hand, and with the right beat upon a drum. The third was a duck, of the natural size, which moved its wings, exhibited all the gestures of that animal, quacked like a duck, drank water, ate corn," &c.

A celebrated machine of this kind, constructed by the younger M. Droz, of the Chaux de Fronds, is thus described by Mr. T. Collinson, in a letter to Dr. Hutton, published in that gentleman's *Mathematical Dictionary*:—"Permit me to speak of another automaton of Droz's, which several years since he exhibited in England, and which, from my personal acquaintance, I had a commodious opportunity of examining. It was a figure of a man, I think the size of life. It held in its hand a metal style: a card of Dutch vellum being laid under it, a spring was touched, which released the internal clock-work from its stop, when the figure immediately began to draw. M. Droz, happening once to be sent for in a great hurry to wait upon some considerable personage at the west end of the town, left me in possession of the keys which opened the recesses to all his machinery. He opened the drawing-master himself, wound it up, explained its leading parts, and taught me how to make it obey my requirings, as it had obeyed his own: M. Droz then went away. After the first card was finished, the figure rested. I put a second, and so on to five separate

cards, all different subjects; but five or six was the extent of its delineating powers. The first card contained, I may truly say, elegant portraits and likenesses of the king and queen, facing each other; and it was curious to observe with what precision the figure lifted up his pencil in the transition of it from one point in the draught to another, without making the least slur whatever: for instance, in passing from the forehead to the eye, nose, and chin, or from the waving curls of the hair to the ear, &c.

M. Malliardet constructed an automaton which exhibited great mechanical skill. It consists of a figure of a boy resting on one knee, and holding a pencil in his hands, with which he executes not only writings, but also drawings, equal to those of the first masters. When the figure begins to work, an attendant dips the pen in ink, and lays the paper on a brass tablet before it, which is adjusted with screws to the proper position. On touching a spring it then proceeds, and when the line is finished it then returns to dot and cross the letters, when this operation is required. In this way it executes four beautiful pieces of writing in French and English, each consisting of several lines; and three drawings of landscapes; all of which occupy about an hour. The figure also exhibits all the motions peculiar to animated existence. The different parts of this machine are put in motion by means of springs; and the outline of its work is effected by the combination of various levers or ellipses traversing the circumference of metal plates or wheels. The edge being cut into different shapes at different places produces a corresponding outline in the communications, modified so as to produce the particular letter or line. The principal motions of the hand are three, two horizontal and one perpendicular, by which the thickening of the stroke by an extremely delicate operation is effected.



The clearness and precision with which a mechanical figure may exhibit specimens of the graphic art is beautifully exhibited in the article AUTOMATON, in which our artist has copied an original drawing made by the figure. The accompanying engraving shows an automaton machine which is now generally considered as a combination of mechanical skill assisted by human art. We have all heard of the automaton chess-player executed by Kempelen, and the above engraving gives its general appearance, while the dotted line shows the probable situation of the human adjunct.

The chess-player of M. de Kempelen consists of a figure as large as life, dressed in a Turkish habit, and sitting behind a table with doors, three feet and a half in length, two in depth, two and a half in height, and running on four wheels. The androides sits on a chair which is fixed to the table or commode; he leans his right arm on the table; in his left he holds a pipe, but with this arm he plays when the pipe is removed, a chess-board of eighteen inches being laid before him. The doors of the commode being thrown open, it is seen to contain wheels, levers, cylinders, and other pieces of mechanism; and in this state the machine is wheeled about the room. The vestments of the automaton are then lifted over its head, and the body is seen full of similar wheels and levers. A little door is opened in its thigh for a similar purpose; after which, every thing being disposed in its place, the automaton is ready to play, and it always takes the first move. At every motion the wheels are heard, the figure moves its head, and seems to look over every part of the chess-board. When it checks the queen it shakes its head, and thrice in giving check to the king. It likewise shakes its head when a false move is made, replaces the piece, and takes the move from the adversary. It generally, though not invariably, wins the game. M. de Kempelen, or his substitute, was always near the machine when it played, and wound it up like a watch after it had made ten or twelve moves. A small square box was frequently consulted by

the exhibitor during the game; and herein, he said, consisted the secret, which he could reveal in a moment.

But we must now pass to the history of mechanics as applied to the construction of horological machinery. Various and many are the ages and persons that claim the merit of having constructed the first machine which measured time by means of gravitating bodies as the moving and regulating powers. Germany, however, certainly is the native country both of clocks and watches. In 1544, a corporation of clock-makers was established in Paris, who secured to themselves a complete monopoly. They effected little indeed towards the improvement of their instruments; neither did any important change take place, until Hooke, in this country, and Huyghens, in Holland, about the year 1658, introduced some valuable innovations. Since that time the art has been approaching to its present accuracy as well in France as in England, and the encouragement held out by the governments of both countries has tended to excite a laudable emulation. The exact measurement of time is the subject of horology. This it is which constitutes the chief utility of the art in civil life, and still more for the purposes of science. Now this is the branch to which the attention of the English has been particularly turned ever since they engaged in it. The mode of reckoning time in which the French persist—that is to say, of admitting into its exact computation the daily variations arising from the obliquity of the ecliptic and the eccentricity of the orbit of the earth, must render superfluous a very steady march of the machines which measure it. A chronometer adjusted to apparent time in November would, if rigorously examined, appear to have lost in February; whereas, in England, the variations of the great luminary which separates day from night are reckoned once for all. In this case the accuracy of the instrument is immediately perceived and valued, while in the former method it is useless, as the thing to be measured has no settled dimensions.

To correct the apparent errors of a chronometer supposed invariable two methods exist: the one is to do as the mechanics of this country have done, to correct the errors of time—that is to say, to suppose a mean sum which shall be invariable; the other is to make the machine follow the errors of time, but this method complicates and loads the works, and is never perfect. Equation watches, showing the difference between mean and apparent time, were originally made in England, but were soon abandoned as inadequate to the end proposed. But the French have persisted in the worst method of correcting the error; and some of their most eminent artists, as the Le Roys, Le Bon, Enderlin, Passemant, and Berthoud, have squandered away as much talent in devising methods of marking both mean and apparent time by the same instrument as if the ends of navigation or the perfection of chronometry could be promoted by success. The utmost that could be gained would be to save, to those who can pay for such machines, the trouble of calculating the daily apparent variations of an instrument too accurate always to be true.

There is another circumstance worth noting in our historical view of the art. In the year 1676, the celebrated Barlow astonished the amateurs by his invention for making clocks and watches repeat the hour at pleasure. But, when the novelty had subsided, few British artists of eminence occupied themselves about it; while, in France, it became a study among the most ingenious and philosophical watch-makers; and they who have excelled in chronometry are they who have done the most to improve repeaters. Hence, then, two English inventions in horology, the one useless, the other luxurious, were soon abandoned in their native country as not congenial with the wants of society, and were seized upon with avidity in France; while here the philosophic branch of the art has been most unremittingly and successfully cultivated.

With reference to the invention of pendulum clocks, it may be proper to state that Huyghens was the first who explained the true relation between the length of a pendulum and the

time of its least vibra ions, and gave a rule by which the time of the rectilineal descent through a line equal in length to the pendulum might from thence be deduced. He next applied the pendulum to regulate the motion of a clock, and gave an account of its construction, and the principles of it, in hi *Horologium Oscillatorium* about the year 1670, though the date of the invention goes as far back as 1656. Lastly, he taught how to correct the imperfection of a pendulum, by making it vibrate between cycloidal cheeks, in consequence of which its vibrations, whether great or small, became not approximately, but precisely, of equal duration.

Robert Hooke, a very celebrated English mechanician, laid claim to the same application of the pendulum to the clock, and the same use of the cycloidal cheeks. There is, however, no real ground of dispute as to the priority of Huyghens's claim, the invention of Hooke being as late as 1670. Of the cycloidal cheeks, he is not likely to have been even the second inventor. Experiment could hardly lead any one to this discovery, and he was not sufficiently skilled in the mathematics to have found it out by mere reasoning. The fact is that, though very original and inventive, Hooke was jealous and illiberal in the extreme; he appropriated to himself the inventions of all the world, and accused all the world of appropriating his. It may be right to add that Galileo conceived the application of the pendulum to the clock earlier, by several years, than either of the periods just referred to. The invention did great honour to him and to his two rivals; but that which argues the most profound thinker and the most skilful mathematician of the three is the discovery of the relation between the length of the pendulum and the time of its vibration, and this discovery belongs exclusively to Huyghens. The method which he followed in his investigation, availing himself of the properties of the cycloid, though it be circuitous, is ingenious and highly instructive. An invention, in which Hooke has certainly the priority to any one, is the application of a spiral spring to regulate the balance of a watch. It is well known of what practical utility this invention has been found, and how much it has contributed to the solution of the problem of finding the longitude at sea, to which not only he, but Galileo and Huyghens, appear all to have had an eye.

In what respects the theory of motion, Huyghens has yet another strong claim to our notice. This arises from his solution of the problem of finding the centre of oscillation of a compound pendulum, or the length of the single pendulum vibrating in the same time with it. Without the solution of this problem, the conclusions respecting the pendulum were inapplicable to the construction of clocks, in which the pendulums used are of necessity compound.

We have now to trace the history of a very important application of the pendulum. This instrument was first proposed as an invariable standard of length by Huyghens; but Derham appears to have been the earliest who made experiments to determine its precise length when employed for that purpose. Desaguliers and Graham also pursued the subject. The numerous difficulties, however, which attended the enquiry, caused it for some time to be abandoned. The author of *Hudibras*, who most vehemently satirized the Royal Society, and especially its active member, Sir Paul Neale, little imagined what would be the result of their labours in this respect when he ridiculed the society's early attempt to form a standard of measure, and accused them of "vapouring that—

> "————————the vibration of this pendulum
> Should make all tailors' yards of one unanimous opinion."

In the year 1774, the Society for the Encouragement of Arts, Manufactures, and Commerce, offered a reward of 100 guineas for a mode of ascertaining invariable standards for weights and measures, communicable at all times to all nations; and, this offer having been continued for three successive years, Mr. John Hatton, a watchmaker, proposed, in March,

1779, to obtain a measure by applying to a pendulum a movable point of suspension, in order to ascertain the difference of length between two portions successively made to vibrate, and measure different known portions of time. Mr. Hatton's attempt, for some cause which does not appear, was not considered by the Society of Arts as entitled to the reward which they had offered, but they presented the inventor with thirty guineas. Some years elapsed without any thing further being done; but, in 1786, Mr. Hatton's plan was taken up by Mr. John Whitehurst, and a machine was constructed by him, an account of which he published in a pamphlet, entitled *An Attempt towards obtaining Invariable Measures of Length, Capacity, and Weight, from the Mensuration of Time, independent of the Mechanical Operations requisite to ascertain the Centre of Oscillation, or the true length of Pendulums.*

Whitehurst's apparatus consisted of a ball suspended by a fine flatted steel wire, forming a pendulum, the length of which could be varied by means of an adjustable clip, attached to a clock which gave motion to the pendulum. The pendulum was adjusted to vibrate forty-two and eighty-four times in a minute, and the distance between the two positions of the clip was marked upon a brass rule, which distance was afterwards determined by Sir G. Shuckburgh to be 59.89358 inches of his standard scale.

In the year 1790, we find the French nation directing its attention to a reform of its system of weights and measures. It appears that much diversity had prevailed, and that several plans of reform had been presented to the government, but not acted upon. A decree was therefore made by the National Assembly on the subject.*

In pursuance of this decree, a commission was named, consisting of Messrs. Borda, Lagrange, Monge, and Condorcet, and their report delivered in 1788 was published in the *Mémoires de l'Académie des Sciences* for 1791. Three fundamental units were considered by the French commissioners:—1. the length of the pendulum vibrating seconds; 2. a quadrant of the equator; and, 3, a quadrant of the terrestrial meridian.

The length of the pendulum vibrating seconds was rejected, on the ground of its depending upon an arbitrary division of the day into 86.400 seconds. It was stated that the regularity of the terrestrial equator was not more certain than the regularity of meridians; and that the extent of the celestial arc corresponding to that measured upon the earth is less susceptible of being determined with precision on the equator than upon a meridian. Finally, that every country has a meridian passing through it, but not an equator.

Without discussing the correctness of these opinions, we shall merely state that a quadrant of the terrestrial meridian was preferred, and the ten-millionth part of it was to be taken, under the name of "metre," as the unit of linear measure. For this purpose it was proposed to measure an arc of the meridian from Dunkirk to Barcelona, comprising more than nine degrees and a half, and this arc was supposed to be of sufficient length for the purpose. At the same time that this resolution was adopted it was determined to make, under the forty-fifth degree of latitude, such experiments as might serve to deduce the number of vibrations which would be made by a pendulum the length of which should be equal to the ten-millionth part of the quadrant of the meridian, in order that this being once known the length of the metre might be recovered by observations of the pendulum.

This grand work was commenced in 1792 by Méchain and Delambre, and carried on,

---

* This document is so important that we quote the words of the reporter to the Assembly:—"Le roi étoit supplié d'écrire à S. M. Britannique, et de la prier d'engager le parlement d' Angleterre à concourir avec l' Assemblée Nationale à la fixation de l' unité naturelle des mesures et des poids, afin que, sous les auspices des deux nations, des commissionaires de l' Académie des Sciences passent se réunir en nombre égal avec des membres choisis de la Société Royal de Londres, dans de lieu qui seroit jugé respectivement le plus convenable, pour déterminer, à la latitude de quarante-cinq dégrés, ou toute autre latitude qui pourroit être préférée, la longueur du pendule, et en déduire un modèle invariable pour toutes les mesures, et pour tous les poids."

amidst the horrors of the revolution, with a perseverance, zeal, and science, which reflect the highest honour upon those engaged in it. Messrs. Biot and Arago were occupied at the same time in experiments on the pendulum; and a few years afterwards these eminent philosophers were directed to extend the meridional observations southward to Formentara, one of the Balearic Isles; and having, by means of general Roy's triangles, extended the arc to Greenwich, the whole comprised an extent of nearly thirteen degrees.

But, however valuable we may consider this work in a scientific point of view, we cannot give it a preference as a standard of measure to the length of the pendulum; and, indeed, the French themselves, though they nominally rejected the pendulum, did, in fact, virtually adopt it as the readiest means by which the metre, if lost, might be recovered. It is true that if two points be determined upon a terrestrial meridian, by means of their latitudes, these points might, if lost, be recovered by repeating the observations.

But, as this depends upon the precise determination of latitude, any circumstance which interferes with this element will materially affect the accuracy of the result. Now, it is well known that the plumb-line will be drawn from its perpendicular position by the attraction of any neighbouring mountain, or by inequality in the density of the surrounding strata. As long as the observations are confined to the same points on the same meridian, we may expect to obtain results differing only by the unavoidable errors of observation; but on any other portion of the same, or under a different meridian, we are liable to errors from local attraction, the amount of which cannot be accurately appreciated. This will sufficiently appear by an examination of the French arc, in the middle of which the length of the degree appears to decrease instead of increasing; and a similar irregularity exists in the arc measured in our own country by lieutenant-colonel Mudge, in the course of the trigonometrical survey, the degrees appearing to decrease in length in proceeding northwards, instead of progressively becoming longer. The anomaly is now known to have been occasioned by a deflection of the plumb-line of the zenith sector, either at Arbury Hill or at Clifton, amounting to more than five seconds. The length of the pendulum also is in some degree influenced by irregularity of density in the atmosphere; but the error to be apprehended in the case of the pendulum is much less than in the determination of the length of an arc of the meridian.

In the *Philosophical Transactions* for 1798, we find a very valuable communication by Sir George Shuckburgh, under the title of *An account of some Endeavours to ascertain the Standard of Weight and Measure.* The author states that he had, as early as the year 1780, taken up the idea of a universal measure, from which all the rest might be derived, by a method similar to that employed by Mr. Whitehurst, and by which all the difficulties arising in determining the actual centre of motion and of oscillation, which had so much embarrassed these experiments, would be got over.

After the death of Mr. Whitehurst, Sir George Shuckburgh obtained the apparatus with which the experiments had actually been made; but, upon attempting to repeat them, the wire by which the ball was suspended (either from rust or some unknown cause) repeatedly broke, after the pendulum had been in action fifteen or twenty hours; and, having tried other stronger wire with no better success, Sir George Shuckburgh was obliged to relinquish the attempt, and to content himself with the accurate measurement of the distance between the marks left by Mr. Whitehurst, indicating the difference of length between the two pendulums, and which was found, as we have before stated, to be equal to 59.89358 inches of his standard scale.

This standard scale was made for Sir George Shuckburgh by Mr. Troughton, who made a copy of it for Professor Pictet: this is the standard which has been taken by all Europe as indicating the linear measure of Great Britain.

In the year 1814 we find another committee of the House of Commons appointed to consider the subject of weights and measures. The report of this committee derives additional interest from its containing the examinations of professor Playfair and Dr. W. Hyde Wollaston, who were called upon by the committee for their opinions as to the best means of comparing the standards of length with some invariable natural standard. These gentlemen were decidedly of opinion that the length of the pendulum was the best standard by which a measure to be kept as a standard of length could be defined by comparison; and professor Playfair recommended that a cube of a given linear measure should be assumed as the unit of capacity, and the same when filled with distilled water of a given temperature as the unit of weight. In consequence of these examinations, the committee made, among others, the following statements:—

That the length of the pendulum vibrating seconds is 39.13047 inches, of which the yard contains thirty-six; and that the standard yard may at any time be ascertained by a comparison either with an arc of the meridian or the length of the pendulum.

That, the standard of linear measure being thus established, the measures of capacity are easily deduced from it by determining the number of cubical inches which they should contain. The standard of weight must be derived from the measures of capacity, by ascertaining the weight of a given bulk of some substance of which the specific gravity is invariable.

That the measures of capacity should be ascertained by the weight of pure or distilled water contained in them, rather than by the number of cubical inches.

That, as the weight of water appears to afford the best and most simple method of checking measures of capacity, it is desirable that all minute fractions of weight should be avoided.

That the most accurate mode of ascertaining the standard pound is to immerse in water a solid cylinder of brass containing 27.648 cubical inches, and to ascertain the difference between its weight in water and its weight in air. The difference between its weight in water and its weight in air, or the weight of the volume of water occupying the same space, is the pound avoirdupois.

In the manner recommended the standard of length is kept invariable by means of the pendulum, the standard of weight by the standard of length and the standard of capacity by that of weight.

A bill founded upon this repor was brought into parliament, and, having passed the Commons, was thrown out of the House of Lords on the motion of the late lord Stanhope. In consequence of the rejection of this bill, and the doubts which existed respecting the true length of the seconds' pendulum, which had been proposed as an invariable standard for measures of length, Mr. Davies Gilbert, in the year 1816, moved in the House of Commons the following resolution:—

"That an humble address be presented to his royal highness the prince Regent, that he will be graciously pleased to give directions for ascertaining the length of the pendulum vibrating seconds of time in the latitude of London, as compared with the standard measure in the possession of this house, and for determining the variations in the length of the said pendulum at the principal stations of the trigonometrical survey extended through Great Britain; and also for comparing the said standard measure with the ten-millionth part of the quadrant of the meridian, now used as the basis of linear measure on a part of the continent of Europe."

In consequence of his royal highness's compliance with the prayer of this address, the astronomer royal was, in the first instance, directed to perform the necessary operations; but, on his requiring further aid, an application was made by his majesty's ministers to Sir Joseph Banks, requesting that the Royal Society would be pleased to afford all the assistance

in their power for the accomplishment of the desired objects. A committee of the Royal Society was in consequence named, consisting, in addition to the president and secretaries, of Sir Charles Blagden, Mr. Davies Gilbert, Dr. Wollaston, Dr. Young, captain Henry Kater, general Mudge, Mr. Henry Browne, Mr. Rennie, and Mr. Troughton. The greater part of these distinguished individuals are now passed to that "bourne from whence no traveller returns," but their labours were of the greatest service to the cause of science. The astronomer royal made some experiments on the French plan for determining the length of the pendulum; Dr. Young proposed a method derived from that of Whitehurst, which appeared unexceptionable, but which, from some difficulties in the execution, was not put in practice; captain Kater availed himself of a property of the pendulum demonstrated by Huyghens and after nearly two years passed in experiments, and in contriving proper apparatus, and methods of observing, succeeded in obtaining the length of the pendulum vibrating seconds by a method free from all objection but the unavoidable and unimportant errors of observation. But, before we proceed, we must endeavour to make our readers understand precisely what is meant by the length of the pendulum, and how it furnishes an invariable standard of measure. And here we must observe that we are not writing for mathematicians, but for the purpose of rendering the subject generally intelligible.—A rod, or any substance suspended from a certain point, and made to vibrate, is called, in common language, a pendulum. Suppose a cylindrical rod or thick wire, fifty-two inches long, to be suspended by one end, and to vibrate; and suppose a small bullet attached to a very fine thread be hung up and also made to vibrate, the distance from the centre of the bullet to the point of suspension being thirty-nine inches. This thread and bullet, and the rod, will make the same number of vibrations in the same time, though the one is fifty-two inches long and the other only thirty-nine. These two pendulums, because they perform the same number of vibrations in the same time, are said to be equal, and the length of *the pendulum* in both cases is nearly thirty-nine inches.

We perceive, then, that in the case of the rod the length of the pendulum is measured from the point of suspension to another point which is distant from it about two-thirds of the length of the rod, and this point is called the centre of oscillation. The length of the pendulum, then, means the distance between the point of suspension and another point, called the centre of oscillation. Now, the place of the centre of oscillation is dependent upon the figure of the body, or upon the arrangement of the parts of which it is composed. Suppose the rod, of which we have spoken, to be furnished with a sliding weight which may be moved upon it. By shifting this sliding weight, the figure of the body, and consequently the place of the centre of oscillation, would be changed, and the rod would no longer vibrate in the same time as before; *the length of the pendulum*, therefore, would be different, though the length of the rod remains the same.

To compute the place of the centre of oscillation, and to find in that way the length of the pendulum, is known to be a problem of extreme difficulty, if not of impossibility. The computation requires that the body employed as a pendulum be of perfectly regular figure, and of uniform density throughout, desiderata which, in the strict sense of the terms, we know to be unattainable. It is not, therefore, surprising that the experiments which were formerly made for determining the length of the pendulum should have led to erroneous results.

Captain Kater's method is free from the embarrassments which arise from irregular density and figure. Let a pendulum be made to vibrate upon a certain point of suspension, and suppose it possible to find its corresponding centre of oscillation. Now, let the pendulum be inverted, and suppose it to vibrate upon its centre of oscillation; the former point of suspension will, under this new arrangement, become the centre of oscillation, and the

number of vibrations in equal times will be the same in either position. This property of the pendulum was first demonstrated by Huyghens.

But of what use, it may be asked, is this theorem, when the centre of oscillation cannot be found? True: but, in the method which we are describing, the centre of oscillation is brought to a point which it is previously decided that it shall occupy. Let the rod of fifty-two inches long have a knife-edge at one end, to serve as a point of suspension, and let another knife-edge, facing it, be fixed in the rod, at about two-thirds of its length from the first; let the rod also be furnished with a sliding weight. Now suspend the rod upon the knife-edge which is at its end, and determine the number of vibrations made by it in twenty-four hours. Next, cause the rod to vibrate upon the other knife-edge, and determine also the number of vibrations made during the same period. This will probably differ from the number in the first position. Shift the weight upon the rod until the number of vibrations, in either position, becomes the same. Having effected this, the one knife-edge being the point of suspension, it is evident from what we have said that the centre of oscillation has been brought to coincide with the other knife-edge; and the distance between the knife-edges, in inches and parts, is the length of the pendulum due to the observed number of vibrations, from which the length of the pendulum vibrating seconds may be calculated without difficulty. The length of the pendulum, therefore, may now be determined at pleasure, with little more trouble than is necessary for the comparison of two standard scales. Captain Kater's experiments are minutely detailed in the *Philosophical Transactions;* and we shall merely state that their result gave, for the length of the pendulum vibrating seconds in vacuo, and reduced to the standard of the seconds' pendulum (which is an invariable standard), an amount equal to 39.13929 inches of the present day, and if we wished at any time to recover the standard we should have, by simple proportion, 39.13929 to 100 as 36 to 91.978 nearly —the length upon the scale which would be equal to our present standard yard.

Having determined the length of the pendulum, captain Kater proceeded to compare the French metre with Sir George Shuckburgh's scale. For this purpose, two bars of platina were sent from France, the one being precisely the length of the metre, and the other having this length marked upon it by two fine lines. These had been verified with the utmost care by M. Arago; and the metre was found to be equal in length to 39.37079 inches of Sir George Shuckburgh's scale. The next object was to determine the variation in the length of the seconds' pendulum, at the principal stations of the trigonometrical survey. For this purpose captain Kater employed an apparatus which gave the *relative* lengths of the pendulum at the different stations; and, knowing the absolute length of the seconds' pendulum at London, he was enabled readily to deduce its length at each station where the experiments were made, with the same certainty as if it had actually been measured there. Several stations were visited, from Unst, the most northern of the Shetland Isles, to Dunnose, in the Isle of Wight; and an account of these operations forms the third part of the *Philosophical Transactions* for 1819.

The French sçavans had employed an apparatus contrived by Borda for determining the length of the pendulum. It consists of a ball of platina, most carefully made, and suspended from a knife-edge by a very fine wire. This mode requires the place of the centre of oscillation to be found; but the great care with which the ball was figured, and the trying it in various positions, enabled these gentlemen to attain an accuracy of result which, from theóry, might have been supposed impracticable.

In the year 1817 M. Biot made experiments at the same stations, at Unst and Leith, which during the following year were visited by captain Kater; and he there determined, by means of Borda's apparatus, the length of the seconds' pendulum, by actual measurement, in parts of the metre. This being converted into English inches, we find that M. Biot's

measurement of the pendulum exceeds captain Kater's determination not quite two ten-thousandths of an inch at Unst, and at Leith falls short of it rather more than that quantity, the mean difference being absolutely insensible. This very near agreement of results, obtained by methods totally dissimilar, authorises the conclusion that the determination of the length of the pendulum vibrating seconds, at London, cannot be far distant from the truth, —a fact which it is of the greatest importance to establish.

Of the various machines of luxury or utility which are in use among civilized nations, none have been more generally adopted than *wheel carriages*, and a brief notice of the history of their construction will very advantageously illustrate the progress of this branch of mechanical philosophy. In some of the colder parts of Europe and America, where ice is to be met with in considerable quantities, sledges are still much in use, as they may be made to pass over the face of a lake, or frozen snow, with nearly as much ease as a plate of smooth metal would upon one of glass.

To understand the advantages which a wheel carriage possesses over these primeval machines, it will only be necessary to bear in mind the different degrees of friction which arise from rubbing and rolling motions, and that in the former of these cases the sliding of a sledge must of necessity generate a degree of friction which will materially retard the motion of the body, but that, when we apply a wheel beneath, the rubbing motion is converted into a rolling operation, and the friction is materially diminished.*

Thus we find that the sledge was speedily superseded by the car, and the latter vehicle by a complete carriage supported on four wheels. But the ancient mechanics rarely paused in the progress of change, and we generally find some most extraordinary attempts to excite the wonder of their contemporaries coupled with each step in the march of really useful improvement. Thus a flying carriage speedily succeeded to a terrestrial anti-attrition machine. Innumerable indeed are the schemes that have been proposed by the learned at different periods, to enable man to support himself in the air by the means of artificial wings, &c., and some of these ingenious contrivances have formed the labours of the most distinguished mechanical geniuses which are recorded in the early annals of science.

Bacon, and an Italian priest named Francisco Lana, endeavoured to accomplish it by means of two thin hollow globes, exhausted of air, which, being considerably lighter than that fluid, were intended to sustain a chair suspended to their lower extremity, and on which the aëronaut might be seated. But Dr. Hook, in a work published some time after the *Prodromo* of Lana, plainly showed the fallacy of the attempt, though without in the least attempting to deny the possibility of eventually effecting this object.

Bishop Wilkins, who was also a disciple of the flying system, describes a species of land-sailing vessels or chariots, which were then commonly used in China: and it is rather a curious fact that a German count, possessing as much of modesty as the generality of foreign

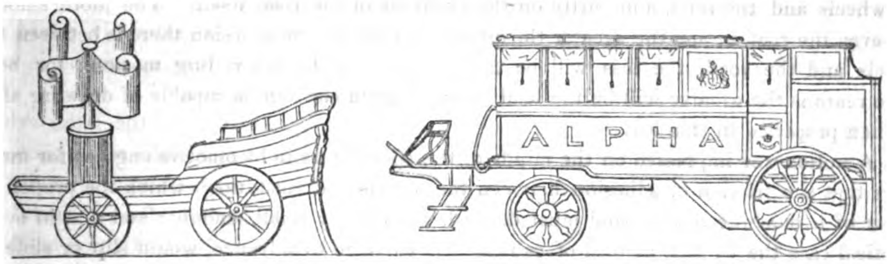
---

* The amount of friction, though not very considerable, in a piece of light wood, may yet be rendered sufficiently apparent if it be placed upon an inclined plane: at a small angle it will not slide down; should, however, a piece of metal of the same weight be substituted for the wood, it will immediately descend. This then shows that the smoother the surface the less the friction.

It will thus be seen that the loss of power from friction may differ very materially in the same machine by the employment of different materials, and Mr. Emerson has shown that when a cubic piece of wood of eight pounds weight moves upon a smooth plane of soft wood, at the rate of three feet per second, its friction is about *one-third* of the weight; but, if it be rough, the friction is little less than *half* the weight. On the same supposition, when both the pieces of wood are very smooth, the friction is about *one-fourth* of the weight; the friction of soft wood on hard, or of hard wood on soft, is *one-fifth*; of hard wood upon hard wood, *one-eighth*; and of polished steel moving on steel, *one-fourth* of the weight. It is also found that dissimilar metals produce the least friction, and of these brass and steel are the best adapted for practical purposes.

mechanics, has lately given to the public, as his own, an invention which has been known in Europe, and occasionally employed in Asia, for the last 400 years.

We may, however, quote a description of one of these sailing carriages from an old work on physics, which will furnish a tolerably good index to their general construction. "The body of the machine should not be large, nor placed very high, not only to prevent overturning, but that its motion may not be thereby impeded; for the velocity will be in proportion to the force of the wind on the sails to that on the body of the machine. Therefore, if they be both equal, it will stand still; or, if the force on the body be greatest, it will go backwards, unless there be a contrivance to lock the wheels. The upper part of the machine may be made to take off when the wind is contrary; and there may be another set of sails placed between the two hind wheels, which will considerably increase its velocity. But after all, for general use, a common carriage must be preferable; for this cannot be expected to go up a moderate ascent without great difficulty; nor down a declivity, when there is a strong wind, without danger; and even on level ground, if the road be rough, its progress must be very slow, attended by both difficulty and danger."



To render this description intelligible we have in the above figure appended a view of one of the best of these carriages, and by its side have placed the great wonder of modern locomotion—a steam carriage.

The employment of an internal mechanism to impel waggons on a plane road is of very early date, but the first application of the steam-engine to this purpose took place, we believe, in the Royal Arsenal at Paris, towards the close of the last century. From this time till 1802 but little progress appears to have been made in the use of this species of wheel carriage; but, about the latter period, Mr. Trevithick commenced a series of experiments on the use of the high-pressure engine for the above purpose. In 1804 a steam-carriage was in operation on the rail-road at Merthyr Tydvil, in South Wales. On the occasion of its first trial, it drew after it as many carriages as contained ten tons of iron a distance of nine miles. It performed this journey without any fresh supply of water, and travelled at the rate of five miles an hour.

It is a singular fact in the history of this invention that much of time and ingenuity were in the first instance vainly expended in attempting to overcome a difficulty which in the end turned out to be purely imaginary. To comprehend distinctly the manner in which a carriage is propelled by steam, let us suppose that the wheels of a common carriage be locked, the carriage being placed on a level road. Let the force be now ascertained experimentally which would be necessary to drag the carriage along the road, the wheels slipping or scraping along the surface. Again, suppose the wheels disengaged so as to be at liberty to revolve; let another carriage be attached to the first, behind it, so that the one cannot proceed without dragging the other along with it; let this other carriage be loaded so that its own weight, together with that of its load, shall be equal to the force which was found necessary to drag the first carriage when the wheels were locked. If the wheels of the first carriage be now turned, by force applied to their spokes or rims, it will be found that they will scrape or

slip on the road. This will be obvious on the least consideration; for the load which is now attached to the carriage, so as to resist its progressive motion, is exactly equal to that which in the former case was sufficient to move the carriage, the wheels being locked. In each case the resistance to be overcome is the friction of the wheels of the first carriage with the road; and consequently, as in the former case it was unable to overcome this resistance, so in the latter this resistance is sufficient to overcome the same load. But, if the weight of the second carriage be diminished so as to be less than that which would be necessary to move the first carriage, the wheels being locked, then, on causing the wheels of the first carriage to revolve by any force applied upon their spokes or rims, the first carriage will necessarily advance, drawing the second after it. This must obviously happen, because the weight of the second carriage is less than that which is necessary to overcome the resistance of the friction between the wheels of the first carriage and the road.

An experiment of this kind will obviously determine the load which any carriage is capable of drawing after it, by the force applied on the wheels to cause them to revolve, and the amount of this load will depend partly on the quantity of adhesion which subsists between the wheels and the road, and partly on the evenness of the road itself. The more smooth and even the road is, and the greater the quantity of friction or adhesion there is between the wheels and the road, the less will be the obstructions to the rolling motion: for both these reasons the greater will be the load which a given carriage is capable of drawing after it when propelled in this way.

A notion was impressed on the minds of the speculators in locomotive engines for many years that the friction or adhesion between the wheels and road, upon which the propelling power of a machine of this kind must depend, was of very small amount; and that in every practical case the wheels, instead of causing the carriage to advance, would slip or slide on the road, or that, if the carriage advanced, still that a portion of the moving power would be thus lost. It is singular that it should never have occurred to these ingenious persons to ascertain by actual experiment the amount of adhesion in any particular case between the wheels and the road: had they done so, we should probably have found at this time locomotive engines in a much more forward state of perfection than that to which they have really attained.

The formation of the Liverpool and Manchester railway may be considered as forming an era in steam locomotion. When this project was undertaken it was not decided what moving power it might be most expedient to adopt as a means of transport on the proposed road: the choice lay between horse-power, fixed steam-engines, and locomotive engines; but the first, for many obvious reasons, was at once rejected for one or other of the last two. It will be obvious that the steam-engine may be applied by two distinct methods to move waggons either on a turnpike-road or on a railway. By the one method the steam-engine is fixed, and draws the carriage or train of carriages towards it by a chain extending the whole length of the road on which the engine works. By this method the line of road over which the transport is conducted is divided into a number of short intervals, at the extremity of each of which a steam-engine is placed. The waggons or carriages, when drawn by any engine to its own station, are detached, and connected with the extremity of the chain worked by the next stationary engine; and thus the journey is performed from station to station by separate engines. By the other method the same engine draws the load the whole journey, travelling with it.

A premium of 500*l.* was offered by the directors for the most improved locomotive engines to run on the Liverpool and Manchester railway, under the conditions that they should produce no smoke, that the pressure of the steam should be limited to fifty pounds on the square inch, and that they should draw at least three times their own weight at the rate of

not less than ten miles an hour, that the engine should be supported on springs, and should not exceed fifteen feet in height. Precautions were also proposed against the consequences of the boiler bursting, and other matters not necessary to mention more particularly here. The proposal was announced in the spring of 1829, and the time of trial was appointed in the following October. The engines which underwent the trial were the *Rocket*, constructed by Mr. Stephenson; the *Sanspareil*, by Mr. Hackworth; and the *Novelty*, by Messrs. Braithwaite and Ericson: of these, the *Rocket* obtained the premium.

A line of railway was selected for the trial on a level piece of road about two miles in length, near a place called Rainhill, between Liverpool and Manchester; the distance between the two stations was a mile and a half, and the engine had to travel this distance backwards and forwards ten times, which made altogether a journey of thirty miles. Great improvement has subsequently been made in the working parts of the engines now running on the Liverpool and Manchester railway, though there is no alteration in their principle, and a corresponding increase of speed and power has been thereby obtained.* One of the engines lately constructed for the Manchester railway ran 23,000 miles with the most trivial repairs, making every day four or five journeys of thirty miles each.

Passing from the steam-carriage as we find it employed on a rail or track road, we come next to consider its usefulness on a common highway. Those who have witnessed the daily journeys of one of these engines by one of the most crowded thoroughfares in the metropolis can have but one opinion as to the ultimate employment of steam power as a medium of transport from one city to another. In a great commercial country like Great Britain, extending as it does its ramifications to every branch of natural and artificial produce, it is almost superfluous to remark that a vast capital is sunk annually in the mere transport of marketable commodities, and which is not only a loss to the seller, as being an unproductive outlay, but entails a heavy increase of expense to the buyer also upon every article of daily consumption. Any means, therefore, that will accelerate the conveyance, and at the same time reduce materially the expense of carriage, offers itself as a national benefit. This desideratum is effected by general locomotive conveyance, and the probability is that the steam power is in this, as well as in many other of its applications, still but in its infancy.

In the attempts which have been made to adapt locomotive engines to turnpike-roads, the projectors have aimed at the accomplishment of two objects: first, the construction of lighter and smaller engines, and, secondly, increased power. These ends, it is plain, can only be attained, with our present knowledge, by the production of steam of very high temperature and pressure, so that the smallest volume of steam shall produce the greatest possible mechanical effect. The methods of propelling the carriage have been in general similar to those used in the railway engines, viz. either by the cranks placed on axles, the wheels being fixed upon the same axles, or by connecting piston-rods with the spokes of the wheels. In some carriages, the boiler and moving power, and the body of the carriage which bears the passengers, are placed on the same wheels. In others, the engine is placed on a separate carriage, and draws after it the carriage which transports the passengers, as is always the case on railways.

* Mr. Stephenson states that a speed of forty miles an hour with a light load has been attained, and that an engine might be constructed to run 100 miles within the hour, although at that velocity the resistance of the atmosphere would be considerable. He further says that engines are now made with eight times the power of the Rocket, yet with little more weight upon any individual point of the rail, the load being equally divided upon six wheels instead of four, and the machinery placed in a more advantageous situation than formerly. Among other improvements is that of making the tubes which form the flues of the boiler more numerous and of smaller diameter than before, and of brass instead of copper. The boiler introduced by Mr. Perkins has also been found advantageous.

The chief difference between the steam-engines used on railways and those adapted to propel carriages on turnpike-roads is in the structure of the boiler. In the latter it is essential that, while the power remains undiminished, the boiler should be lighter and smaller. The accomplishment of this has been attempted by various contrivances for subdividing a small quantity of water, so as to expose a considerable quantity of surface in contact with it to the action of the fire: spreading the water in thin layers or flat plates—inserting it between plates of iron placed at a short distance asunder, the fire being admitted between the intermediate plates—dividing it into small tubes, round which the fire has play—and introducing it between the surfaces of cylinders placed one within another, the fire being admitted between the alternate cylinders. All these plans have been resorted to by different projectors; but without tracing the various steps in the history of steam locomotion by which a rude and heavy machine has been converted into a light and elegant carriage, fitted almost for every degree of velocity, it may be enough to state that a committee of the House of Commons came to the conclusion "that the substitution of inanimate for animate power is one of the most important improvements in the means of internal communication ever introduced."*

The art of *building* is indebted, in a very extraordinary degree, to the labours of the scientific mechanic. With respect to the origin of architecture, and the several periods to which its advances towards perfection are to be referred, it would be a waste of time to enter into an enquiry of any great length. The great antiquity of building is self-evident. When men first felt the inclemencies of the season it had its beginning, and has spread wherever the severities of climate demand a shelter or a shade. Its rudiments may be traced in the hut of the Indian, and the Greenlander's cave, as well as in the proudest temples of ancient Greece. It is easy to conceive that, in the early stages of society, genius had expanded but little. The architect's first efforts were but vague, and the structure he erected simple, perhaps no more than a number of trees, leaning together at the top, in the form of a cone, interwoven with twigs, and plastered with mud, to exclude the weather. In this early period we may also suppose each desirous to render his own habitation the

---

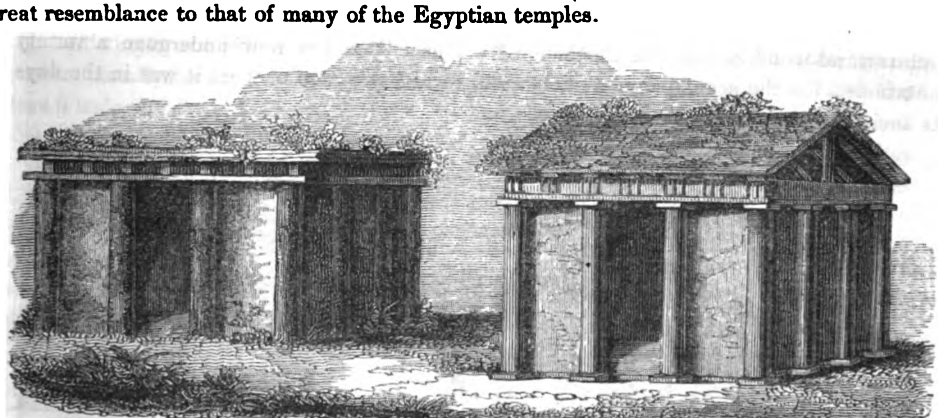
* It has been argued, with some show of truth, that the introduction of the steam-carriage will have the effect of injuring the agricultural interests; but the answer given by Colonel Torrens, in his evidence before a committee of the House of Commons, is so lucid and convincing that we readily avail ourselves of it to illustrate the advantages of steam locomotion. Having been requested by the committee to state his reasons for believing that agriculture would be benefited by the substitution of inanimate for animal power, he answered, "I conceive that agriculture is prosperous in proportion as the quantity of produce brought to market exceeds the quantity expended in bringing it there. If steam-carriages be employed, instead of carriages drawn by horses, it will be because that mode of conveyance is found the cheapest. Cheapening the carriage of the produce of the soil must necessarily diminish the quantity of produce expended in bringing a given quantity to market, and will therefore increase the net surplus, which net surplus constitutes the encouragement to agriculture. For example, if it requires the expenditure of 200 quarters of corn to raise 400, and the expenditure of 100 more on carriage to bring the 400 to market, then the net surplus will be 100. If, by the substitution of steam-carriages, you can bring the same quantity to market with an expenditure of fifty-quarters, then your net surplus is increased from 100 to 150 quarters, and consequently either the farmer's profit or the landlord's rent increased in a corresponding proportion. There are many tracts of land which cannot now be cultivated, because the quantity of produce expended in cultivation and in carriage exceeds the quantity which that expenditure would bring to market. But, if you diminish the quantity expended in bringing a given quantity to market, then you may obtain a net surplus produce from such inferior soils, and consequently allow cultivation to be extended over tracts which could not otherwise be tilled.

"On the same principle, lowering the expense of carriage would enable you to apply additional quantities of labour and capital to all the soils already under cultivation. But it is not necessary to go into any illustrative examples to explain this, it being a well-known principle that every improvement which allows us to cultivate land of a quality which could not previously be cultivated also enables us to cultivate in a higher manner lands already under tillage."

most attractive, as well as the most convenient. Here, then, we find the first dawn of architecture as a fine as well as a useful art.

At a very early period, as might be expected, architecture had made some progress; for we are informed, in holy writ, that Cain "builded a city, and called the name of the city after the name of his son, Enoch; but we are wholly in the dark as to the perfection to which it had attained when that awful visitation of the Almighty, the universal deluge, obliterated almost every mark of previous habitation. The next mention of it is in the account of the building of the tower of Babel, which was stopped by the confusion of tongues. This was soon surrounded by other buildings, and walls of great magnitude, and here, therefore, we may date the origin of post-diluvian architecture. Whatever celebrity, however, the wonders of Babylon attained among the ancients, no remains of them have come down to us, and it is the massive edifices of Egypt, built apparently rather for eternity than time, that now excite our admiration as the most ancient as well as stupendous structures existing upon earth. We must not however, under this epoch, omit to notice the remains, and, alas! the only remains, of Indian and Mexican greatness. But for the splendid ruins at Delhi and Agra, and that most singular specimen in the island of Elephanta, we should scarcely have known of the existence of civilization among the ancient Hindoos; and the aborigines of Mexico were regarded as little better than savages before the late discoveries by Mr. Bullock. The dates of these buildings are wholly unknown; but, from the great similarity they bear to those of Egypt, it is supposed they are of at least equal antiquity.

It may not be improper here to remark that the latter country is considered to have been peopled by a colony from India. About the same general date may also be classed the architecture of the Hebrews, or, as it is more properly characterized, the Phœnician style, the greatest monument of which was the far-famed temple of Solomon. The description of this edifice as it occurs in the sacred text will be found, on an accurate consideration, to bear a great resemblance to that of many of the Egyptian temples.



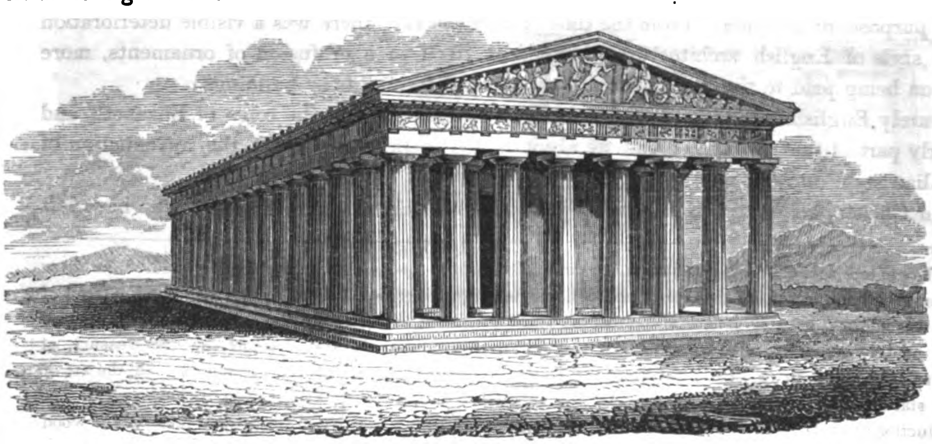
In the accompanying sketches one figure furnishes a view of what may be considered as the first attempts of the uneducated artisan, regardless only of strength in the erection of his edifice, and the second will serve to illustrate the advance towards a higher style of art, and when the modern mode of combining strength and ornamental design in a roof had been discovered. It is obvious that the first step would be to remove the foliage of the tree which was ultimately to form the walls of the edifice, and then to employ the larger boughs to construct the roof. From this follows a species of cornice for ornamenting the top line of the

edifice, and we ultimately find the pediment and "jutting frieze" giving a definite architectural form and finish to the whole. This brings us to the first dawn of Grecian art; and now the column of polished marble succeeded to the rough and unhewn tree, and the chiselled ornament took the place of a garniture of boughs. The sister art of painting was also soon introduced.

The architecture of a people is an important part of their history. It is the external and enduring form of their public life, an index to the state of knowledge and social progress. Some persons, indeed, have regarded the noblest monuments of antiquity but as the marks of "a slavish submission to a hierarchy." But it may safely be asserted that the progress which man has made in the arts is mainly due to the influence of religious systems, and that the great improvements which have thus been gradually effected have at last descended to the humblest dwellings.

Temples formed by human hands, though under the immediate direction of the Deity, have been raised to perpetuate the forms of worship earliest known on the earth; and, when that worship was degraded by a substitution of the creature for the Creator, we still find the noblest energies of man engaged in the erection of similar edifices. Civil architecture made but little progress till the time of Pericles, when some of the noblest efforts of human ingenuity were executed at Athens. This celebrated city was the capital of Attica, in Greece. The city was covered with magnificent temples; and, whilst the spoils which resulted from her conquests in Persia furnished the means for a most profuse expenditure, it was fortunate for mankind that the highest taste directed the outlay of its rulers. The most ancient part of the city of Athens was built upon a rock called the Acropolis, and contained the most sumptuous buildings with which Athens was adorned. The monuments called the *Elgin Marbles* formed part of the fragments of these edifices; and we need hardly add that they are now preserved in the British Museum in a way as praiseworthy to the nation as it is to the taste of its government.

Athens contained many splendid temples; but the greatest wonder in this world of architectural wonders was the Parthenon.* This edifice has now undergone a variety of mutations; but the accompanying sketch will furnish a notion of what it was in the days of its ancient greatness.



It may here be proper to remark that the earliest edifices of Greece were by no means remarkable for beauty, as even the temples were little better than rude huts, sheltered, if

* Phidias, the principal architect employed in the erection of this magnificent structure, was the great master of the art of statuary. He was born at Athens about 480 years before the Christian era. Athens was at that

sheltered at all, by branches of laurel and other trees. On the decline of Greece, and its conquest by the Romans, the arts appear to have been transferred to the conquerors; but among that hardy and warlike race it made little progress before the reign of Augustus. Under the auspices of that munificent monarch it rapidly attained to almost as great perfection as in the favoured country of the arts in its best days, and the "eternal city" owes much of its present estimation to the noble structures erected by him and his successors. With Rome, however, the art decayed, and was overwhelmed in the general confusion and oblivion of learning, art, and science.

The existing monuments in Great Britain which are supposed to be anterior to the Roman invasion of this island are classed, whether correctly or not we shall not here enquire, under the general term Druidical or Celtic. The most remarkable of these monuments, both for preservation and arrangement, is Stonehenge, on Salisbury Plain, in Wiltshire. Here we find stones of very large dimensions, placed upright in the ground, and forming a series of concentric circles. They are not merely rude masses, like those of Avebury and Silbury Hill, but they have evidently undergone some sharping and rubbing down, so as to form tolerably regular parallelopipedons. We here observe also two stones placed upright, like posts or pillars, and another large stone placed over them, like an architrave or lintel; the lintel is also secured by means of mortises and tenons. All this indicates certainly a regular principle of construction. The attention of the Saxons in our own country, probably about the eighth century, was excited by the remains of edifices raised by the Romans during their residence in England. These, in their newly erected churches, they aspired to imitate; but their workmen, ignorant of the principles which guided the architects of those splendid ruins, produced only the general outlines of their patterns; and those clumsy forms continued to be practised, with little alteration, till the beginning of the twelfth century. But now, as the tumult excited by the invasion subsided, and the genius of the nation improved, a taste for the fine arts began to show itself, and architecture assumed a different and novel aspect. Instead of tamely treading in the steps of their predecessors, the architects of those times devised a style as scientific as it was grand, and as beautiful as new. The pointed or Saxon style, usually termed Gothic, is peculiarly fitted for ecclesiastical edifices; and the long-drawn aisle and fretted screen, with its dim and shadowy light, are admirably adapted for the purposes of devotion. From the time of Edward III., there was a visible deterioration in the style of English architecture, which lost itself in a profusion of ornaments, more attention being paid to the details than to the general forms of the buildings.

Purely English architecture made but little progress during the reign of Elizabeth and the early part of that of James; and we are indebted to Inigo Jones for the introduction of the Italian style into our edifices.*

Sir Christopher Wren, Kent, and Wyatt, are the only modern architects who have left

period the general school of arts and letters. From Homer, whose poems Phidias had deeply studied, he drew images of greatness, which he afterwards moulded with earthly materials in a kindred spirit; and the mind of Phidias was adorned with all the knowledge which could be useful to his profession. He was also skilled in history, poetry, geometry, and the optics of that day; and, whilst Pericles commanded the treasury at Athens and the allied states, he had the means of giving full scope to the efforts of his genius. In the art of forming statues of bronze, both for the number and excellence of his works, Phidias was without a rival. In the production of ivory statues also he stood alone; nor did he disdain to work in the meaner materials of wood and clay, or to execute articles of the smallest mechanism. Among the most celebrated of the works which Phidias executed with his own hands was a statue of Minerva, which adorned the interior of the Parthenon.

* This distinguished English architect was born in 1572, and apprenticed to a joiner; but, having distinguished himself in landscape painting, he was sent to Italy by the earl of Pembroke, who was at the expense of his education. His principal work, the Banqetting-house at Whitehall, still remains an enduring monument of his genius, and the style that he first introduced into this country.

works which will outlive the periods of their erection. The greatest work of the latter gentleman, in Gothic architecture, was Fonthill Abbey, the merits of which building, when we consider that the architect had no model to work from, are truly extraordinary. The purest taste formerly reigned throughout the whole of this splendid structure; and Mr. Britton, in his graphic delineations, has presented to succeeding professors a legacy of incalculable value.

We have seen that the remains of Grecian architecture and statuary, which have escaped the ravages of time, and descended to us in somewhat of a perfect state, continue to be viewed with enthusiastic admiration, even after every attempt which the most skilful modern artists have made to rival or exceed them. Their basso-relievos, their coins, their gems and cameos, are not of less admirable execution; and there is much reason to believe that in painting they were not less eminent, although, from the perishable nature of the specimens of this branch of the arts, but few models have descended to us, and none of these probably of much intrinsic value. This leads us to the connection which must of necessity subsist between the arts of painting and architecture, as well as sculpture. Among the ancient paintings employed in architectural edifices which have reached modern times, the principal have been some specimens of fresco, rescued from the ruins of Adriana, Herculaneum, and Pompeii, on which it cannot be supposed that much graphic skill would be employed. To these we have to add the Aldrobandine nuptials, the figures on the pyramid of Cestius, a figure of Rome on the palladium, and some similar performances, which we cannot suppose to have been works of the highest value. It would, therefore, be unreasonable, from the evidence which we possess, to refuse to the early architects that pre-eminence in painting which they undoubtedly possessed in the corresponding branches of the arts of design. On this subject Sir Joshua Reynolds, with truth, remarks that "there can be no doubt but that the same correctness of design was required from the painter as the sculptor; and if the same good fortune had happened to us in regard to their paintings, to possess what the ancients themselves esteemed their masterpieces, which is the case in sculpture, I have no doubt but we should find their figures as correctly drawn as the Laocoon, and probably coloured like Titian. What disposes me to think higher of their colouring than any remains of ancient painting will warrant is the account which Pliny gives of the mode of operation used by the celebrated Apelles. In regard to their power of giving peculiar expression, no correct judgment can be formed; but we cannot well suppose that men who were capable of giving that general grandeur of character, which so eminently distinguishes their works in sculpture, were incapable of expressing peculiar passions.*

The causes of the remarkable pre-eminence to which the ancients attained in the fine arts, particularly in sculpture, statuary, and architecture, form an interesting subject for speculation. One obvious advantage of the *antique* imitation of the human form arose from the frequent opportunities which the artists enjoyed of viewing nature either entirely undraped or veiled only with light and graceful clothing. At the gymnasia, or public places where the youths performed the various feats of running, wrestling, boxing, and leaping, they had an opportunity of studying the finest examples of the natural and graceful play of the muscles, and had exhibited before them every variety of posture and attitude, with a dignity and expression which cannot now be obtained. Another essential advantage which the ancient works of art possess over modern productions is that they were generally works of much longer time. Among the ancients, it was thought a great deal for one sculptor to have executed four or five statues in the course of his life; hence the high finish of the most

---

* See *Sir Joshua Reynold's notes upon Fresnoy.*

celebrated marbles of antiquity, which bears the minutest inspection, and the trial of every different light. It was likewise no small advantage to possess an unoccupied field, in which the exertions of genius were unfettered and free from the reproach of imitation. A modern artist labours under the disadvantage of a comparison with the fine models of antiquity, which, while he despairs of surpassing, he is compelled, by the tyranny of taste, in some measure to copy. Nothing can more cruelly damp the ardour of invention, or check the generous emulation to excel. We ought not, however, to allow our admiration of the antique to transport us too far, or to blind us to the faults which appear even in the statues of Greece and Rome, while we refuse a just tribute of applause to the exertions of our most esteemed modern artists. There is undoubtedly the greatest dignity and beauty in many specimens of the antique which we possess; but sometimes this is obtained at the expense of animation and just expression. "The ancient sculptors," says Sir Joshua Reynolds, "neglected to animate the features, even with the general expression of the passions. Of this, the group of boxers is a remarkable instance; they are engaged in the most animated action with the greatest serenity of countenance. This frequent deficiency, in ancient sculpture, could proceed from nothing but a habit of inattention to what was considered as comparatively immaterial."

It is said that Michael Angelo, desirous of exposing the undue predilection in which the classical antique was held in his time, formed with great care a statue of Cupid, which he buried in a spot where he was sure it would be found, after having broken off one of its arms. The Cupid having been dug up, all the world pronounced it to be an antique, and resounded with its praises; till the modern artist having produced the arm, which fitted exactly to the defective trunk, the connoisseurs were compelled, however reluctantly, to acknowledge their blunder. An intimate acquaintance with ancient sculpture and architecture implies something more than a skilful discrimination between what is truly beautiful and classical and what is fantastic or deformed. It implies, also, a knowledge of the different styles of the artists, the manners of the various ages, and the different kinds of materials on which the various arts have been practised, whether wood, clay, ivory, precious stones, marble, flint, or metal. The study of the antique has served to prove that the ancients had attained to wonderful skill in the arts of metallurgy, pottery, gem-engraving, founding, moulding, &c.; and in many respects seem rather to have excelled than to have fallen short of the most ingenious productions of the modern workshop. It was said by the late Mr. Wedgewood, who was doubtless the most skilful manufacturer of porcelain of modern times, that the celebrated Barberini vase afforded evidence of an art of pottery among the ancients, of which we are as yet ignorant even of the rudiments.

Some of the most beautiful works of modern sculpture have been employed to ornament the new palace in St. James's Park, as well as in the various public statues which have been erected in the squares of the metropolis; and it is gratifying to observe the growing taste which exists for blending architecture with the other branches of the fine arts. Our space will not however permit of our pursuing this matter further, and an estimate of the comparative degrees of excellence obtained by ancient and modern artists will be found under the articles FINE ARTS and SCULPTURE.

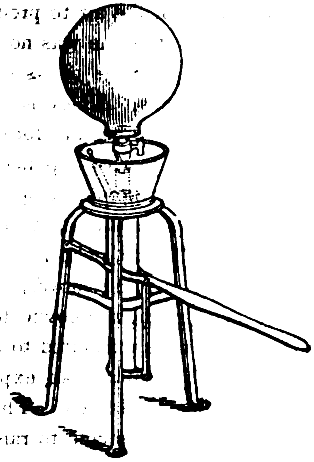
We may now proceed to trace the history of our acquaintance with the mechanical properties of the *air or atmosphere* which surrounds our globe. This is a very interesting branch of human knowledge, and as important to the chemical as to the pneumatic philosopher. Some of the properties of the air in which we live and breathe were well known to the ancient philosophers. Thus Aristotle says that all the elements have weight, with the exception of fire; adding that a bladder inflated with air will weigh more than when quite empty. Plutarch and Strobæus quote Aristotle as teaching that the weight of air is between that of fire and

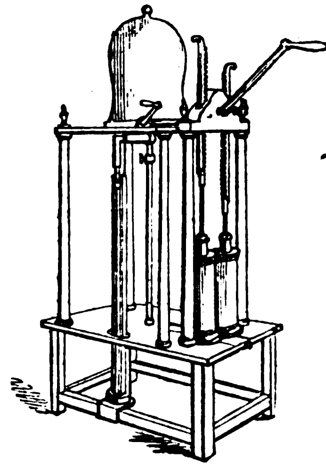
earth; and the latter philosopher himself quotes Empedocles as attributing the act of respiration to the pressure of the air, by which it insinuates itself into the lungs. Hero of Alexandria, in his work entitled *Spiritalia*, applies the principle of the elasticity of the air to produce and explain various effects, in such a way as sufficiently to convince us that he was no stranger to the properties of atmospheric air; and Ctesibius, adopting the principle of its elasticity, constructed wind-guns, which afterwards passed for modern inventions. There is, however, some difference between the ancient and modern air-guns. In that of Ctesibius, for example, the ball was not immediately exposed to the action of the air, but was impelled by the longer arm of a lever, while the air acted on the shorter; but the principle of operation is the same in both, and shows clearly that the elasticity of common air, if it could not be accurately measured, was at least well known at that period. Hero, who is now generally considered as the first who employed high-pressure steam as a prime mover, describes several ingenious pneumatic instruments. The effects which are now known to result from the weight and elasticity of the atmosphere were for a long time attributed to the imaginary principle of what was called "nature's abhorrence of a vacuum," an explanation which does not appear to have been called in question till the time of Galileo. This philosopher had studied the operation of a sucking-pump, which had been erected to raise water out of a cistern; and he was surprised to find that when the water descended to a certain point the pump ceased to act, and continued to lose its power by any further subsidence of the fluid. After reflecting for some time on this singular fact, Galileo attributed the rising of the water to the attraction between the piston and the fluid particles. Dr. Young says that "before Galileo's time, it was generally supposed that water was raised in a sucking-pump on account of the impossibility of the existence of a vacuum; if, however, a vacuum had been impossible in nature, the water would have followed the water to all heights, however great: but Galileo found that the limit of its ascent was about thirty-four feet, and concluded that a column of this height was the measure of the magnitude of the atmospheric pressure."

It occurred to Torricelli, in the year 1643, that, whatever might be the cause by which a column of water thirty-four feet high is sustained above its level, the same force would sustain a column of any other fluid which weighed as much as that column of water on the same base; and hence he concluded that, as quicksilver is about fourteen times as heavy as water, it could not be kept up at a greater height than twenty-nine or thirty inches. He then made the experiment still called after his name. He provided himself with a glass tube, about three feet long, and sealed it hermetically at one end, and, having filled it with mercury, he closed it at the open end with his finger, and inverted it in a basin of mercury. Upon withdrawing his finger, he had the satisfaction of seeing the column of mercury descend and settle at the height of between twenty-nine and thirty inches in the tube. He was still, however, not aware that the phenomenon was to be attributed to the pressure of the atmosphere, although after a little reflection he fell upon that explanation; and, after he had fully convinced himself of the truth of his hypothesis, it is said that, with a feeling of generosity of which we have few examples, he expressed his regret that it had not fallen to the lot of his master, Galileo, to have completed a discovery of which he had first laid the foundation.

The invention of the air-pump is the most important feature in the history of pneumatics, and Otto Guericke has justly been considered its first constructor; yet it was our own countryman Boyle who turned the instrument to useful purposes. In the hands of Otto Guericke the air-pump was a pleasing pneumatic toy: but in those of Boyle it became a valuable philosophical instrument. The value of modern mechanical improvements in this branch of science will, however, be best understood by graphic views of both pumps: the

first an accurate sketch of the apparatus as it was employed by Otto Guericke, and the other representing the improved apparatus as it is now constructed.





Otto Guericke formed a vacuum by fitting a piston in a barrel, which he immersed in a tub of water, and then raising the piston he formed an imperfect vacuum beneath it. In his subsequent experiments he placed the apparatus on a tripod stand, and discontinued the use of the water. It may be proper to state that motion was in the first instance given to the piston by a stirrup beneath. Now with this apparatus he performed many pleasing experiments, but never converted it to any really philosophical purposes.

The improved air-pump has two pistons made to fit accurately in brass barrels, and motion is given to them by a lever and two racks, so that when one is raised the other is depressed. By this beautiful mechanical arrangement the pressure of the atmosphere is equal in both barrels, and, when the pump is put in operation, a child's force will accomplish as much as could be effected by a strong man with the old apparatus.

The barometer is a pneumatic instrument which may certainly be said to date its history from the Torricellian experiment. Mariotte in France, and Boyle and Townley in England, found from experiment that the density of the atmosphere was proportional to the compressing weight; but this law is true only when the temperature of the air remains constant. Attention, however, was not then paid to this important restriction, which in fact could not be indicated by experiments where the compressed volumes of air differed but little from each other in respect to temperature. The law of compression being otherwise known, Halley made use of it for calculating the decrease of density in the beds of the atmosphere at different altitudes, and thus led to the mathematical formulæ by means of which the difference of altitude of two places may be calculated from the heights of mercury in the barometer observed at each of them. Newton, in his *Principia*, perfected Halley's theory, by showing that regard was to be paid to the diminution of gravity according as the distance from the surface of the earth increased. But, what is very remarkable in so scrupulous an observer of the laws of nature, he also, as well as Halley, omitted to consider the effect of the variations of heat, and of the progressive decrease of the temperature and density of the different strata of the atmosphere. The barometrical formulæ thus obtained, without the correction which renders them applicable to all temperatures, could only furnish a very imperfect approximation; and therefore philosophers and mathematicians who endeavoured to apply them found that they succeeded only in a few instances, and that generally the results seemed to be subject to various errors, which appeared to follow no uniform law.

M. de Luc discovered the true source of these anomalies, by searching in the observations themselves for the correspondence between the temperature of the air and the correction which the general formulæ required. Numerous experiments on the comparative expansions of air and mercury enabled him to perceive the law that those corrections ought to follow, and the quantity in all cases which should be assigned to them. This remarkable discovery, by giving to the barometrical formulæ an unexpected accuracy, animated the zeal of philosophers, and observations were multiplied to a great extent. Dr. Maskeleyne undertook to reduce the new formulæ into English measures, while Playfair added a correction to the variation of gravity in different latitudes. Sir George Shuckburgh, by very exact measures, verified the results of M, de Luc, and gave them a greater degree of precision. General Roy also made an application of it at a great number of places in the progress of his survey. The heights of the principal mountains in the Alpine chain were ascertained by M. M. Saussure and Pictet, the Pyrenees by M. Ramond, and the Andes by Humboldt. The barometer is now considered as valuable an instrument for measuring the heights of mountains as for foretelling the changes of the weather, and it is rendered so portable that a complete mountain barometer can be enclosed in a case very little larger than a common walking-stick.

The principles of the science of *acoustics* must be placed in connection with the subject we have now been discussing. The transmission of sound and the mechanism of audition were but little understood prior to the middle of the last century. Aristotle, deriving his information probably from the tenets of the Pythagorean school, seems to have formed tolerably just notions of the theory of harmonics. The language of that philosopher was so much corrupted, however, and disguised by ignorant transcribers, that Galileo, who not only studied music as a science, but practised it as a delightful art, may be fairly allowed to have rediscovered the general doctrines of harmony. Mersenne and Kircher afterwards made a variety of most ingenious experiments, which, though rather neglected at the time, tended greatly to extend the science. But it was reserved for the genius of Newton to sketch out the true theory of sound. In his *Principia* he illustrates the experiment of aërial pulses, and by a fine application of dynamics, conducted with his usual sagacity, he succeeded in calculating their celerity of transmission. The solution which he has given of this intricate problem is far, however, from being unexceptionable in the form and mode of reasoning. Instead of attempting to embrace all the conditions affecting the problem in a differential equation, for which, indeed, his fluxionary calculus was not yet far enough advanced, he proceeds less boldly, and only arrives at the conclusion by an indirect process and a sort of compensation of errors.

The velocity of sound was determined with considerable accuracy and on a great scale by Cassini and Maraldi, while employed in conducting the trigonometrical survey of France. During the winter of the years 1738 and 1739 these astronomers repeatedly discharged at night, when the air was calm and the temperature uniform, a small piece of ordnance from their station on Mont Martre, above Paris, and measured the time that elapsed between the flash and the report, as observed from a signal-tower at the distance of about eighteen miles. The mean of numerous trials gave 1130 feet in one second for the velocity of the transmission of sound.

About the same time Condamine, who was sent with the other academicians to ascertain the length of a degree in Peru, took an opportunity of likewise measuring the celerity of sound at two very different points. He found this was 1175 feet on the sultry plain of Cayenne, and only 1120 on the frozen heights of Quito. It was obvious therefore that the rarefaction of the air in those lofty regions had in no important degree affected the results. Compared with what had been observed in France, the velocity of the aërial pulses had

somewhat diminished at Quito by the prevailing cold, but was on the other hand considerably augmented by the excessive heat and moisture which oppress Cayenne.*

Mr. Goldingham, who made a series of experiments on the velocity of sound at Madras, considers that for each degree of the thermometer 1.2 foot may be allowed in the velocity of sound for a second, for each degree of the hygrometer 1.4 foot, and for one-tenth of an inch of the barometer 9.2 feet. He concludes that ten feet per second is the difference of the velocity of sound between a calm and in a moderate breeze, and twenty-one feet and a quarter in a second, or 1275 in a minute, is the difference when the wind is in the direction of the motion of the sound or opposed to it.

The process of hearing is certainly very remarkable, and well calculated to excite our surprise and curiosity, when we think of that infinite variety which we observe; single sounds, varying in intensity from the gentlest whisper to the noise and violence of an explosion; continued sounds, from the ripple of waters to the roar of the cataract; strains of melody which enchant the ear, rising from grave to acute, and falling again to the lowest in the compass; or those harsher notes which only grate in their discord. Can it be possible that all these diversities arise from the agitations in the air, differing only in the manner in which they strike the ear, in the force and quickness of their action, or in the regularity of their succession? What incredible sensibility in this organ, to perceive and be moved by such imperceptible shades of gradation, and to recognise such infinite diversities in kind! The powers of the eye in discriminating the minutest shades of colour justly excite our astonishment; but each colour presents a peculiar modification of light. The powers of the ear must appear still more extraordinary, if every sensation in it arises merely from a mechanical agitation of the same nature in every case, but only differing in the force of the impulse. Yet this is really the case; and the more we examine into the subject the more clearly does it appear demonstrable by the laws of geometry and mechanics.

That the air is the ordinary vehicle of sound is clearly proved by the beautiful experiment of enclosing a bell within the receiver of an air-pump, and then exhausting the air. As the process of exhaustion proceeds, the sound is observed to become continually fainter and fainter, until at last it dies away altogether. The bell, however, continues to ring: at least the hammer continues to strike, and thereby agitate the bell, as before; and yet no sound is emitted, plainly because there is no medium to convey the agitation to the ear. If the sound in this experiment cannot be altogether extinguished, this will be found to arise from the impracticability of exhausting the air altogether out of the receiver, and also of insulating completely the bell from the plate of the air-pump on which it stands, the support serving to convey the sound even after the air is exhausted. A very good mode of performing this experiment is to have a bell with a small piece of clock-work attached to it, which strikes at regular intervals, and with a tone of uniform intensity.

In order to conceive the mode in which sound is propagated through the air, let us consider what takes place when we move a series of balls ranged in a line on a table, or suspended

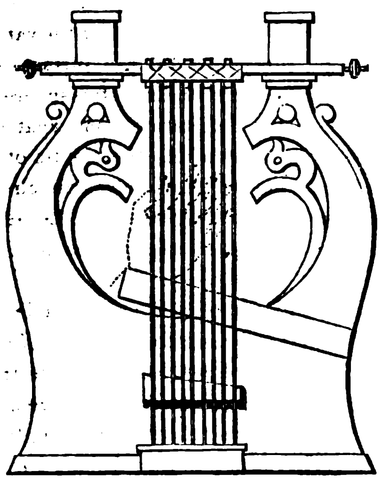
* The distance at which sounds may be heard is much greater than is generally imagined. Dr. Derham informs us, on the authority of S. Averrani, that at the siege of Messina the report of the guns was heard at Augusta and Syracuse, almost 100 Italian miles distant; and he also states that in the naval engagement between the English and the Dutch, which took place in 1672, the report of the guns was heard upwards of 200 miles off. Humboldt mentions the reports of volcanoes in South America heard at the distance of 300 miles; and Dr. Thomson states, on the authority of a friend, that the loud explosions which took place from the volcano in St. Vincent's were heard distinctly at Demerara: now this is a distance which must considerably exceed 300 miles. On the other hand, again, sound is enfeebled and dissipated sooner in alpine regions: thus, the traveller, roving at some height above a valley, descries with uncommon clearness perhaps a huntsman on the brow of the opposite mountain, and, while he watches every flash, yet can he scarcely hear the report of the fowling-piece.

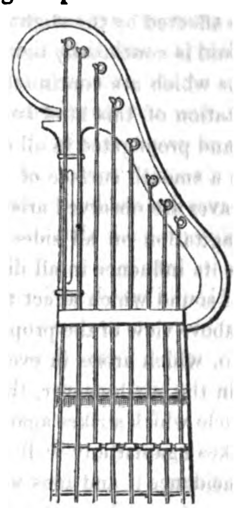
by threads. If we strike the one end of the line, by impelling a ball against it, it is only the ball at the other end which appears to be affected. This flies off from the rest, and leaves them almost stationary. The intermediate balls, therefore, serve merely to transmit the impulse from the one end to the other of the series. In the same manner it is that the agitation or impulse from which sound arises is transmitted through the air. This fluid, like every other body, consists of an almost infinite number of small particles, a single series of which may be represented to us by the balls in the above example. These particles are not even in contact with one another: they are separated by minute intervals, but are yet connected together by attractive and repulsive forces, which tend to retain them perpetually in equilibrio. In every case, therefore, there is in reality a series of such particles reaching from the sounding body to the ear. The former by its agitation strikes that particle which is next to it, the intermediate ones serve to convey the impression, and the last one, flying off, strikes the sentient organ of hearing. The ear then forms merely a sort of organ of touch, but of such exquisite sensibility that it becomes affected by the slightest agitation in the fluid atmosphere by which it is surrounded. But this fluid is continually agitated, and in a thousand different ways, by the various motions and actions which are continually going on among the bodies on the surface of the earth. Every agitation of this kind communicates itself to the surrounding atmosphere; it is by it conveyed and propagated in all directions from the centre of agitation, somewhat like what we observe in a smooth surface of wa terwhen a stone is thrown into the middle of it—a series of small waves are observed arising and propagating themselves in concentric circles from the centre of agitation on all sides. In a similar manner every agitation in the aërial medium propagates its influence in all directions, and from these varied impressions arise all those diversities of sound which affect the ear.

The above view of the propagation of sound explains at once the remarkable phenomenon of the echo, which arises in every case from obstacles opposing the progress of sound. The agitation in the air however, though interrupted by such obstacles, is not destroyed: each aërial particle which strikes against the opposing surface is reflected from it like an elastic ball which strikes against any wall or table. The sound is thus reflected at an angle equal to the angle of incidence; and it is when a number of these reflected impressions are thrown back to the point whence the original sound issues, by the configuration of the opposing obstacles, as so frequently happens among rocks, walls, &c., that an echo is produced.

The celebrated Chladni, whose loss will be deplored, not only in Germany, but by all who feel the importance of the study of the supreme law of nature by the analogy of its different elements, showed many years since that the vibrations of sounds put in motion grains of sand, united on a glass plate, in such a manner that when the tones are pure the grains unite in regular forms, and when they are discordant the grains trace upon the glass figures without symmetry. His latest discovery previous to his death was that of the manner of the propagation of sound, by means of applying the theory of liquid waves to that of aërial ones. When a sonorous bar of metal or glass is plunged into a liquid surface, four currents are observed round this bar, two of which are in the direction of the vibratory movement, and the others perpendicular to the direction of the former. Two currents are eccentric or flying, and two concentric or returning, and between them is formed an oval movement; and from these phenomena we may imagine what passes in the waves of the air, and explain the interruption of sound in certain directions where the waves take a compound course, viz. when they pass from the centrifugal to the centripetal movement. Nothing is so highly satisfactory as this analogy when shown to exist in different elements, an analogy which it has been the especial merit of the Germans, and of none more than Chladni, to inculcate as one of the fundamental principles to be borne in mind in the study of nature.

A very moderate acquaintance with the science of acoustics must have sufficed to enable the ancient musicians to construct their instruments, as they were usually of a very simple character, and as they rarely produced more than five or six different tones. The invention of the organ by Ctesibius forms a remarkable epoch in this branch of acoustical science. The larger wind instruments were furnished with hydraulic bellows, the smaller with bellows of leather only; and they had keys which were depressed, like those of the modern organs, by the fingers of the performer, and which opened valves communicating with the pipes. The early stringed instruments did not, however, make so rapid a progress, as the notes produced by the harp even in the last century were fixed and determined by a small number of cords attached to the sounding body. Exceptions did however occasionally occur to this rule, and we have even seen the sculptured remains of an early Grecian lyre in which an arrangement existed for changing the disposable length of the string. This was effected by a sliding bar, which might be moved by the musician during his performance.





This was a great step in the march of improvement, and an instrument of this description is carefully delineated in the above figure. But when we come to compare it with the instrument placed by its side we shall readily appreciate the value of modern improvement. In the harp-lute, or lyre, which forms the accompanying figure, there are only eight strings, and yet four-and-twenty distinct tones may be formed by the agency of small sliding levers; and, in the most perfect form of the harp, nearly 500 tones may be elicited by the same means. The apollonicon invented by Mr. Flight combines every other really valuable species of musical instrument within one range; and a series of vibrating metallic tongues have lately been combined so as to form a valuable wind instrument.

Hydrostatics may be said to date its origin from the time of Archimedes; he ascertained the laws which determine the weight of bodies immersed in fluids, and also the position which they would assume in floating on them. According to some authors, the work which Archimedes composed on hydrostatics we owe, as it now exists, to a translation from the Arabic; while others maintain that we have derived it from an immediate translation of the original Greek text. This work is divided into two books. The basis on which this author founds his theory is this: that every particle of a fluid being supposed equal, and equally heavy, will remain in the place in which it is found; or that the whole mass will remain in equilibrio when each particular particle is equally pressed in every direction. This equality of pressure, on which the state of equilibrium is made to depend, is demonstrated by experiment. The author afterwards examines the conditions which ought to obtain in order

that a solid homogeneous body, floating on a fluid, may take and preserve the situation of equilibrium: he shows that the centre of gravity of the body, and that of the body immersed, must be situated in the same vertical right line; that the weight of the body is equal to the portion of fluid displaced by it; that the body will be entirely immersed when its specific gravity is equal to, or exceeds, that of the fluid; and he also examines nearly all the other principles of the science of hydrostatics, which constitute the basis of our present knowledge on the subject. It appears, likewise, from his investigations, that two bodies of equal magnitude, both heavier than the fluid in which they are immersed, will lose equal parts of their weights; and that, reciprocally, when the weights lost in the same fluid are equal, the bodies are of equal magnitudes. The solution of the well-known problem of Archimedes, relative to the crown of Hiero, king of Syracuse, depends on the above principles. Besides the theoretical principles of hydrostatics, we owe also to this philosopher, according to some authors, an ingenious hydraulic machine, called from the name of its supposed inventor *the screw of Archimedes*. Diodorus asserts that this philosopher invented it in his voyage to Egypt, and that the natives of that country afterwards employed it for the purpose of draining the extensive marshes with which it abounds; but Vitruvius, a contemporary of Diodorus, does not enumerate it amongst the discoveries of Archimedes, of whom he was nevertheless a great admirer; and Claudius Perrault, the translator and commentator of Vitruvius, adds that the use Diodorus gives to this machine (namely, that it was employed to render Egypt habitable, by draining off the waters with which it was formerly inundated) makes it highly probable that the engine is of much earlier date than the time of the Syracusan philosopher.

The early philosophers believed that water was absolutely incompressible, and it was not till the middle of the seventeenth century that this doctrine was attempted to be controverted. The members of the Florentine academy tried the compression of water in three different ways, which are described in the account of their experiments printed in 1661. 1. Having provided two glass tubes, terminated by hollow balls, they filled the one partly, and the other to excess, with pure water, and joined the tubes hermetically, so as to form one piece. Then, applying heat to the first ball, till the water boiled, they forced its vapour to press against the column in the other stem. But no contraction of the fluid took place, though a copper ball was afterwards substituted; and, when the action of the heat was still further urged, the tube at last burst with violence. 2. Into a glass tube, immediately above six pounds of water, they introduced eighty pounds of quicksilver, without causing any diminution of volume. 3. Their most celebrated experiment was, having filled a hollow silver ball with water by a small hole, afterwards soldered accurately, to give it a few smart blows with a hammer, when, far from suffering compression, the water was seen to ooze or pass from the pores of the silver. Mr. Boyle, whose practice it was to repeat the more striking experiments made on the continent, had a round tin or pewter vessel filled carefully with water, and tightly plugged; the blow of a wooden mallet beat it flat; but, on piercing the tin with the point of a small nail, the confined water instantly sprang to the height of two or three feet. About the year 1752, Dr. Peter Shaw, who read public lectures in London, exhibited a strong copper ball of four inches in diameter, and filled with water by a small orifice, into which a screw was fitted, and forced to enter by turning an iron arm or lever: the globe was partly opened by this enormous squeeze, and the water spouted from the crevice as from a fountain. These experiments all concur to show that water is capable of sustaining an immense pressure without undergoing any very sensible contraction; but they prove, at the same time, the actual existence of such a contraction, since the projecting of the water, after a crack has once begun in the vessel that confines it, could only proceed from the evolution of an internal repulsive force.

The compressibility of water was first satisfactorily demonstrated by the ingenious Mr. Canton in 1762, by a very simple and conclusive experiment. To a glass ball, of rather more than an inch and a half in diameter, he joined hermetically a tube about four inches long, and having a bore equal to the hundredth part of an inch. The relative capacity of this ball, and of the stem, he ascertained by introducing mercury, and weighing nicely its separate portions. The stem was then marked by the edge of a file into divisions, corresponding each to the hundred-thousandth part of the whole capacity of the ball. This instrument was now filled with distilled water, carefully purified of its adhering air, and placed under the receiver of an air-pump: on producing an exhaustion, the water appeared instantly to swell, rising four divisions and three-fifths in the stem, or a space nearly equal to the mercurial expansion corresponding to half a degree of heat on Fahrenheit's scale. In a condensing engine, the water sunk just as much, for each additional pressure of an atmosphere,—the ball remaining always at the same temperature, or at the fiftieth degree of Fahrenheit. Since the stem was left open, the pressure exerted by the air, both on the inside and outside of the instrument, must in all cases have been precisely the same; and consequently the glass had no disposition to alter its figure and modify the results. The contraction or expansion produced was, therefore, confined wholly to the body of water and to the thin shell of glass, of which indeed the influence might be rejected as insignificant. It was hence decided that the purest water suffers a visible concentration, or a diminution of its volume, under a powerful compression. But, in the course of his experiments, Mr. Canton observed a curious circumstance, that water is more compressible in cold than in warm weather. Thus, the contraction, under a single incumbent atmosphere, amounted to 4.9 divisions when the thermometer stood at 34°, but was only 4.4 divisions when the heat rose to 64°. This singular fact might afford room for speculation; but it were better, in the mean while, to repeat the experiment again with more delicacy, and on a greater scale.

The compression of some other fluids was likewise measured in the same way. The contraction, under the weight of an atmosphere, and at the ordinary temperature, amounted, in millionth parts of the entire capacity of the ball, to sixty-six with alcohol, to forty-eight with olive oil, to forty with sea water, and only to three when mercury was employed.

In 1779, professor Zimmerman of Brunswick printed a short account of some trials made by him and Abich, director of the salt-mines, with a press of a particular construction, consisting of a water-tight cylinder of very thick brass, with a piston nicely fitted, to be pushed down by means of a long lever, at whose extremity different weights were appended. Rain-water being introduced into the cavity was subjected to an enormous pressure, equivalent to that of 313 atmospheres, and had its volume then diminished between one thirty-fifth and one thirty-sixth part. This quantity gives, for the effect of a single incumbent atmosphere, a condensation amounting to seventy-five millionth parts, instead of forty-six, as found by Mr. Canton. The excess was no doubt owing to the distention of the brass cylinder, which, with all its strength and solidity, would yet partially yield to the action of such a prodigious force. This circumstance renders the experiment somewhat unsatisfactory, and the influence of friction must likewise affect the accuracy of the calculation. The effect of such distention is easily witnessed in the case of glass. If a large bulb of a thermometer be suddenly squeezed between the finger and thumb, the mercury will start up in the stem perhaps several degrees, and will again sink as quickly after the pressure is removed. To prevent any derangement from communication of heat, the hand may be covered with a thick glove. But the fact can be shown in a less exceptionable way: let a mercurial thermometer, with a large bulb and a long stem, be first held upright, and then immediately inverted; between these two positions the column of mercury will descend through a visible space. This apparent change of volume has been hastily supposed by some

experimentalists to mark the compressibility of mercury, which could not be sensible but under the action of a column of incomparably greater height.

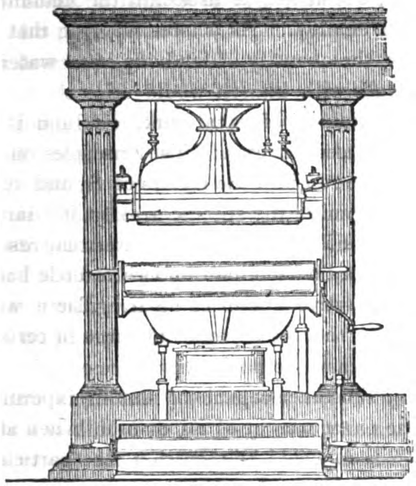
Mr. Perkins, a most ingenious mechanic, well known for the number and variety of his experiments, employed an instrument called a *piezometer*, to ascertain the amount of compression in different fluids. He subjected this instrument to a force equal to that of about 326 times the ordinary pressure of the atmosphere; and he found that the water it contained had been increased about three and a half per cent.

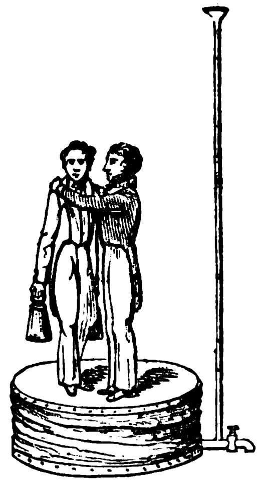
The clepsydra, or water-clock, acts upon purely hydrostatic principles; and it was employed as a means of measuring time at a very early period. The principles on which it should be constructed will be examined under the article HYDROSTATICS; and it may be enough to state that the French annals mention a curious water-clock, sent by Aaron, king of Persia, to Charlemagne, about the year 807, which, it would seem, bore some resemblance to the clocks now in use: it was of brass, and showed the hours by twelve little balls of the same metal, which at the end of each hour produced sounds from a bell. There were also figures of twelve cavaliers, which at the end of each hour came out through certain apertures, or windows, in the side of the clock, and shut them again.

The most obvious law of hydrostatics, and one on which nearly all our experiments are founded, is this, that the surface of every homogeneous gravitating fluid, when at rest, is horizontal. If any part of the surface were inclined to the horizon, the particles would necessarily tend towards its lowest part, in the same manner as if they moved without friction on the inclined surface of a solid. And if any two portions of the surface of the fluid be separated, as in two branches of a tube, or pipe, however they may be situated, the fluid cannot remain at rest unless the surfaces be in the same level plane; for, if we imagine such a tube, containing water, to be made of ice, and to be immersed in a large reservoir of water, and then thawed, the water will make a part of the general contents of the reservoir: and it is obvious that the tube has acquired no new power of supporting it by being thawed: consequently the water would remain in a state of equilibrium at the same height in the tube. The experimental proof of this proposition is easy and obvious, and the property affords one of the most usual modes of determining a horizontal surface. But, when we compare the heights of fluids occupying tubes of different magnitudes, it is necessary, if the tubes are small, to apply a slight correction on account of the actions of the tubes on the fluids which they contain, which are more apparent as their diameters are smaller. There is a very singular paradoxical experiment illustrative of this part of our subject. It is this, that any quantity of water, or any other fluid, however small, may be made to balance and support any quantity, or any weight, how great soever. Thus, water in a bent pipe, or canal, open at both ends, always rises to the same height at both ends, whether those ends be wide or narrow, equal or unequal. And since the pressure of fluids is directly as their perpendicular heights, without any regard to their quantities, it follows that whatever the figure or size of the vessels may be, provided their heights be equal, and the areas of their bottoms equal, the pressures of equal heights of water are equal on the bottoms of those vessels, even though the one should contain a thousand, or even ten thousand times as much as the other.

When a machine is constructed expressly for the purpose of showing, in the most striking manner, that the pressure of fluids is as their perpendicular heights, and that a quantity, however small, may be made to support a weight or another quantity however large, it may be most advantageously made by the apparatus called the hydrostatic bellows. This ingenious machine was much employed by the early experimentalists, under the name of the *paradoxical instrument;* it was however in truth rather employed to excite the admiration of the vulgar than to elucidate the principles of hydrostatical science. The bellows are shown

in operation in the subjoined figure; two or three persons may readily be placed on a small pair of bellows and actually elevated by a few ounces of water.





To illustrate this singular experiment, we may suppose a hole to be made in the upper part of the board, and another tube to be inserted there; the water would certainly rise to the same level in them both; and, supposing the board to be filled with tubes, the water would attain the same level in them all, because a series of pipes would, in fact, form a solid cylinder of water. If we suppose the hole to be of the same diameter as the interior of the tube, and fitted with a piston, then, if the tube contained two ounces of water, the piston would sustain a weight of two ounces without being depressed. If the area of the hole were twice that of the bore of the tube, two ounces in the tube would sustain four ounces on the piston. In this manner, every part equal to the bore of the tube is pressed upwards with a force equal to the weight of fluid in the tube. Hence, if the proportion subsisting between the area of the tube and that of the bellows be multiplied by the weight of water in the tube, the product will express the force with which the boards are separated.

Turning from this very demonstrative scientific toy to the practical application of the principle it exhibits, in the useful arts, we may refer to the machine placed in juxta-position to the "paradoxical instrument." This exhibits a combination of powers surpassing that of any other simple hydrostatic apparatus. A pressure equal to fifty or sixty tons may readily be put in operation by a single labourer. We are indebted to Mr. Bramah for the invention of this press, and, in the case before us, it is applied to the dyeing and pressing of linen. In this apparatus, Mr. Bramah suggested the use of a very strong metal cylinder, in lieu of the bellows part of the apparatus, the leather of which would be incapable of resisting any very considerable pressure. A piston or plug was so arranged as to move water-tight in the cylinder; and, as a substitute for the high fluid column, he employed a small forcing-pump for raising the water, and thus the pressing column becomes indefinitely long, although the whole apparatus is of itself comparatively small. Taken as a whole, Bramah's press may be considered as one of the most important discoveries in modern times.

That branch of the science of hydrostatics which relates to the *specific gravity* of bodies may be said to date its origin from the time of Archimedes. Hiero, king of Syracuse, is said to have employed an artist to make him a regal crown of gold, and furnished a sufficient quantity of pure metal for that purpose. When the crown was finished, its weight was found to equal that of the gold delivered for it; yet the king suspected an adulteration, and,

vapour is generated by the application of a lamp placed beneath. As the steam ascends from the cauldron it enters the ball by the hollow axes, and ultimately rushes from the two small apertures exhibited in the engraving. From this it will be seen that the action of Hero's steam apparatus must be precisely similar to that of the rocket-wheel, only high-pressure steam is substituted for inflamed gunpowder.*

Without tracing the various steps by which this "potent commander of the elements,—this abridger of time and space," has acquired its present high degree of perfection, it may be enough in the present place to state that we are mainly indebted to the celebrated James Watt for those improvements by which it has become a patient drudge in every branch of our manufactures, and served the cause of humanity most effectually by substituting inanimate power for muscular exertion.

The use of water as an impelling power, both for the turning of machinery and other purposes connected with the useful arts, appears to have been known at a very early period. Vitruvius describes a variety of machines for this purpose, the earliest of which were employed merely to raise a portion of the fluid by which they were impelled. The most simple method of applying this element as a mechanical agent evidently consisted in the construction of a wheel, the periphery of which was composed of float-boards. This, on being exposed to the action of a running stream, was afterwards employed to give motion to a variety of mills. But few improvements have been effected in the construction of these machines; and, though we now apply their powers to a greater variety of purposes, they are yet in point of principle nearly identical with those employed in the time of Vitruvius.†

Sextus Julius Frontinus, who was inspector of the public fountains at Rome, published a valuable work on the conveyance of water by aqueducts; he describes those which the Romans had constructed, and the dates of their erection. He then fixes and compares with each other the measures of capacity which he employed at Rome for ascertaining the products of the ajutages. On these subjects he made several correct observations: thus, for example, he showed that the quantity of water issuing from an ajutage did not wholly depend upon its magnitude, but that the height of the reservoir above it must also be considered. He showed also that the tube designed to carry off part of the water of an aqueduct ought to have,

* At first view, the power of Hero's apparatus would appear exceedingly small; but the editor has a model which he employs in his public lectures which is nearly as powerful as a small high-pressure engine of the same size.

† A distinguished French writer on hydrodynamics, when speaking of these monuments of human genius, asks, "to whom do we owe all these useful and important discoveries? What honours, what recompenses, have these benefactors of man received of their country or the world at large? History commonly answers nothing to these enquiries; while great pains are taken to transmit the names and exploits of conquerors who have ravaged the earth and left traces of misery and destruction in all their steps." These observations of Bossut apply pretty generally to every age of scientific discovery; and it is but justice to the government of Napoleon Buonaparte to remark that he set the example of bestowing honours and dignities on those most celebrated for their scientific eminence. We have somewhat tardily followed in the march of justice to these best benefactors of mankind, and the present century has to record the names of Davy, Herschel, Brewster, and Bell, as instances of men whose services have received the meed of their country's praise, and obtained its well-earned honorary distinctions.

permanent than those which have undergone that process. A remarkably good red ink is obtained as follows:—A quarter of a pound of the best logwood is boiled with an ounce of pounded alum, and the same quantity of cream of tartar, with half the quantity of water, and, while the preparation is still warm, sugar and good gum-Arabic, of each one ounce, are dissolved in it. Solutions of indigo with pieces of alumina, and mixed with gum, form a blue ink. Green ink is obtained from verdigris, distilled with vinegar and mixed with a little gum. Saffron, alum, and gum-water, form a yellow. It is not well ascertained how soon the present kind of writing-ink came into use. It has certainly been employed for many centuries in most European countries; but the ancient Roman inks were, for the most part, of a totally different composition, being made of some vegetable carbonaceous matter, like lamp-black, diffused in a liquor. Sometimes the ink of very old writings is so much faded by time as to be illegible. Doctor Blagden (*Philosophical Transactions*, vol. 77) in his experiments on this subject, found that, in most of these, the colour might be restored, or rather a new body of colour given, by pencilling them over with a solution of prussiate of potash, and then with a dilute acid, either sulphuric or muriatic; or else, *vice versâ*, first with the acid, and then with the prussiate.

INLAND NAVIGATION. A general account of CANAL NAVIGATION has already been given under that head; and a view of river navigation will appear under RIVERS. We now purpose giving a general view of the canals in Canada. Those of the United States of America will be noticed in their several geographical divisions, as they are too numerous to be brought into one article.

Welland Canal was constructed between the years 1824 and 1829. Its length is forty-one miles and a half; its breadth at the surface fifty-eight feet, at the bottom twenty-six feet, and its depth eight feet. This line of navigation passes from the mouth of Ouse River, on Lake Erie, north-eastward, to strike at a point of the Welland or Chippewa River; and, taking the course of that river, downwards, eleven miles, proceeds thence northward, across the mountain ridge, and down to the mouth of Twelve-Mile Creek, on Lake Ontario. The distance from lake to lake is forty-three miles. The deepest cutting, near the summit, is fifty-six feet. It has thirty-five locks, one hundred to one hundred and twenty-five feet long, twenty-two to thirty-two feet wide. The capital stock of the company is 200,000*l.*; the number of shares 16,000. This canal admits of sloop navigation, and opens a communication between Lake Erie and Lake Ontario in the same vessels, which are thus enabled to navigate those lakes without discharging and reloading cargoes. One of the purposes of its construction was, to prevent the trade of that part of Upper Canada which communicates with the great western lakes from being diverted to New York, by the route of the Erie Canal. It was an arduous and stupendous work, as appears sufficiently from the dimensions and length of the canal. Its execution was, however, facilitated by taking advantage of natural channels of slack-water.

La Chine Canal is ten miles in length, from Montreal, on the St. Lawrence, directly to Upper La Chine, on Lake St. Louis, cutting off a bend in the river, and avoiding the rapids of St. Louis. Cost, 220,000*l.*; for sloop navigation.

L'Isle Perrault Canal is a projected work of five miles in length, from St. Louis Lake, at the foot of St. Anne's rapids, to the head thereof, by a canal, passing either at the back of St. Anne's or else across the Isle Perrault.

Grenville Canal is a projected work of twelve miles in length, from the head of Long Sault, or Ottawa falls, at the village of Grenville, by a lateral canal to the foot of Carillon rapids, opposite Point Fortune; for sloop navigation. Estimated cost, 250,000*l.*

La Petite Nation Canal is a projected artificial channel of navigation, of fifty miles in length, from the foot of Carillon rapids, at Hawkesbury, on the Ottawa, across the peninsula, to the St. Lawrence, at Prescott.

The *Rideau Canal*, which is now just completed, is described, and a view of its locks given, under the cut CANADA, in the Second Division of this work.

INSTRUMENT, in *music;* any sonorous body, artificially constructed for the production of musical sound. Musical instruments are divided into three kinds—wind-instruments, stringed instruments, and instruments of percussion. Of the stringed instruments among the ancients, the most known are the lyre, psalterium, and trigonium; the principal wind-instruments are the tibia, fistula, tuba, cornu, and lituus; those of percussion, the tympanum, cymbalum, and crepitaculum.

INSTRUMENTAL MUSIC; music produced by *instruments*, as contradistinguished from vocal music. The term *instrumental* is particularly applied to the greater compositions, in which the human voice has no part. The first instrument invented was probably the pipe or flute. An idle shepherd might very naturally, from accident, or in imitation of the effects of the wind, blow through a simple reed, and thus invent the pipe, from which the flute would readily originate. The pipe is, in fact, found among many savages. The invention of stringed instruments, as they are more artificial, is of later origin. The instrumental music of the Greeks was confined to a few instruments, among which the flute, the cithara, the sackbut, though not precisely like those instruments among the moderns, were the most important. The violin was invented in the middle ages, and soon became the principal instrument, taking place above the flute, though the latter is of much more ancient origin, because the playing on a stringed instrument is less fatiguing, and the tone of the violin is more distinct from the human voice, and therefore better fitted to be used with it; besides, the instrument permits much more perfect execution. Until the middle of the last century, the Italian composers used no other instruments in their great pieces than violins and bass-viols; at that time, however, they began to use the hautboy and the horn; but the flute has never been much esteemed in Italy, particularly in music exclusively instrumental. These were the only wind-instruments in Italy, used in instrumental music, until the end of the last century; and even to this day the Italians use wind-instruments much less than the Germans, and particularly the French. Since Mozart, every instrument has been used which appeared adapted to answer a particular purpose. This is the cause of the fewness of the notes in the Italian, and of their great number in German, and their excess in the modern French scores. In general, symphonies and overtures, solos, duets, terzettos, quartettos, quintettos, &c., sonatas, fantasias, con-

cerios for single instruments, dances, marches, &c., belong to instrumental music.

INSURANCE is a contract whereby, for a stipulated consideration, called a *premium*, one party undertakes to indemnify another against certain risks. The party undertaking to make the indemnity is called the *insurer* or *underwriter*, and the one to be indemnified the *assured* or *insured*. The instrument by which the contract is made is denominated a *policy;* the events or causes of loss insured against, *risks* or *perils*; and the thing insured, the *subject* or *insurable interest*. *Marine* insurance relates to property and risks at sea; insurance of property on shore against fire is called *fire* insurance; and the written contracts, in such cases, are often denominated *fire* policies.

There was a kind of insurance in use among the Greeks and Romans, called *bottomry* or *respondentia*, which is where the owner of a vessel or goods borrows money upon bottomry, upon the vessel, or upon respondentia on the goods, for a certain voyage, agreeing that, if the ship or goods arrive at a certain port, the money shall be repaid, and also interest, exceeding the legal rate; but, if lost by the risks specified in the bond before arriving at the port named, the lender is to lose the money loaned. This risk of losing the whole capital is the cause of the excess of interest allowed in case of the arrival of the ship or goods; and it is called *marine interest*, which ought to be equal to the common rate of interest added to the rate of premium for insuring the ship or goods for the same voyage against the same risks. This sort of contract was anciently in use, and, as the laws then gave less security, or, at least, as credit and confidence were not so widely diffused, and correspondence was less extensive among merchants, it was usual for the lender to send some person with the property, to receive repayment of the money loaned and the marine interest, at the port where the risk terminated. In modern times, it is not usual to send any person with the property, who would not be of service during the voyage; and, at its termination, some agent of the lender, at the port of arrival, if he is not there himself, looks after his interest.

The wide extension of correspondence, among merchants in all parts of the world, in modern times, gives a facility for this purpose, and renders the execution of this, as well as other commercial contracts, more economical, and at the same time more secure. But contracts of insurance, strictly so called, are of modern invention; and their importance, in relation to commerce, is scarcely inferior to that of bills of exchange. Every merchant is liable to losses and reverses, by the change of the markets. The risks of this description may, however, be calculated upon with some degree of probability; but those of fire, the perils of the seas, or capture, cannot be so well estimated; and, when they come, they would, in many cases, bring ruin upon the merchant, if it were not for the system of insurance, the object of which is to apportion the losses from these disasters among all those whose property is exposed to the same hazards. If, for instance, all persons engaged in trading were to enter into a general agreement to contribute for the losses of each other, occasioned by those casualties, in the proportions of the amounts that they should respectively have at risk, every individual would then only run the risk of the proportion of losses occurring upon the general aggregate of property at risk. But as such a general combination would be complicated, and practically inconvenient, a very simple system is devised, by means of insurance, for effecting the same object; for one person—the underwriter—agrees to take upon himself those risks for a hundred merchants, more or less, for a certain premium on each risk, calculating that the premiums on the fortunate adventurers will compensate him for the losses he may incur on those which are unfortunate, and leave him some surplus, as a compensation for his time and trouble; and a little experience will enable him to calculate the chances with very considerable accuracy. The result accordingly is, that all the persons who procure their property to be insured by him, in effect, mutually contribute for each other's losses, by the bargain of each with the common receiver of the contributions of all. This contract was subjected to a system of definite rules much earlier in Italy and France than in England; and, as the contract is the same in principle and very similar in form in different countries, the rules of construction adapted to it in one country are equally applicable in another.

Insurances on human life may now be noticed. The duration of life, over which the most healthy and the most temperate man has no certain control, must necessarily appear a matter of chance when individually considered. If, however, we regard the human species in masses, we are enabled to ascertain with considerable precision the average of life; and thus to apply a system of insurance, not to life itself, for that is, of course, dependent upon a higher power than man, but against the injurious consequences which proceed from the death of those upon whom the support of others depends. If we take ten millions of people, for instance, and ascertain the age to which each person arrived previously to his death, by dividing the total of their ages by the number of individuals, we establish the average term of the duration of life. This term varies in particular countries and under different states of society; but it is invariably found to increase with the increase of the means of comfort. The average term of life in Great Britain is thus longer, by almost one-third, than it was during the last century. The rate of mortality in 1780 was one in forty; in 1821 it was one in fifty-eight. Vaccination, and the great improvements in medical science, have doubtless contributed to this result. To establish data for determining this mean length of life has been an important object with statesmen, of late years, and forms a great branch of the science of statistics. The tables which have been constructed upon the experience of most European nations enable us, not only to determine the average term of life, but the probabilities of the number of years a person of any particular age has to live. Upon these calculations is founded the system of life-assurances and annuities; and the various corporations which grant life-assurances are enabled to conduct their operations upon a just and solid foundation, in proportion as they form their estimates upon averages equally supported by science and experience. To all persons whose income is not permanent, and who are unable to lay by a sufficiency to prevent the lamentable consequences to their children of an inadequate provision, the principle of life-assurance offers a safe and effectual remedy against the chances of mortality, which no prudent father should forego, if the annual sacrifice

sides, so that the liquid portion filtrates through it slowly, and water is occasionally added, as the filtration proceeds, until a quantity of liquid has passed through ten times the weight of the sub-carbonate of potash employed. The lime in this process attracts the carbonic acid, and from the large quantity employed, and the slowness with which the water holding the alkali dissolved passes through it, the abstraction is more complete than could be obtained by any other simple arrangement.

Though the potash obtained by this process is nearly pure, it is not perfectly so; a little carbonic acid remains combined with it, and there may also be present small portions of sulphate and muriate of potash, and silicious earths. To obtain it in a state of purity, different methods have been proposed; that which is generally followed is one proposed by Berthollet. Potash is soluble in alcohol, but is insoluble when combined with carbonic or sulphuric acid. The alkaline solution, therefore, obtained by slow filtration from the mixture of sub-carbonate of potash and lime, is evaporated until it becomes of a thick consistence, and there is then added to it an equal weight of alcohol. A quantity of undissolved matter subsides; a dark-coloured liquid floats above this, which is principally water holding dissolved potash combined with carbonic acid; a lighter coloured liquor is above this; it is drawn off, and is partially evaporated in a silver bason. On standing, it separates into two liquids of different specific gravities, the heavier being a solution of the alkali with carbonic acid, the lighter a solution of pure alkali. The latter is poured off, and is evaporated, so that on cooling it shall either deposit crystals or pass into an irregular crystallized mass; a small portion of residual liquor being poured off, the potash is thus obtained in a solid form. Potash thus prepared is obtained by evaporation in a solid mass, hard, and brittle, of a grayish-white colour. If evaporated to a less extent, it crystallizes in forms which are modified by the degree of evaporation; it is thus obtained in thin plates, in slender needles, or in tetrahedral pyramids, single or double, these containing different portions of water of crystallization.

Potash is an alkali of considerable strength: a minute portion of it changes the blue and purple colours of vegetables to a green, and it is so powerfully corrosive as quickly to erode and dissolve animal matter. It unites with oils and fats, forming soaps, which, though concrete, are soft and gelatinous. See Soap.

It is under the form of sub-carbonate of potash that this salt is afforded in the processes by which it is usually obtained, as in the incineration of the wood of plants. It therefore forms the base of the potash or pearl-ash of commerce, which also contains, however, other saline substances, particularly sulphate and muriate of potash, and earthy and metallic matter. From these it is in part freed, by dissolving the pearl-ash in an equal weight of warm water; the foreign substances, being sparingly soluble, remain in a great measure undissolved; the clear liquor is poured off, and is evaporated until a pellicle appears on its surface; on cooling and remaining at rest for a few hours, it deposits a little muriate of potash, and, being poured off from this and evaporated, the sub-carbonate is obtained.

The process for obtaining pot and pearl-ash is given by Kirwan as follows:

1. The weeds should be cut just before they seed, then spread, well dried, and gathered clean.

2. They should be burned within doors on a grate, and the ashes laid in a chest as fast as they are produced. If any charcoal be visible, it should be picked out, and thrown back into the fire. If the weeds be moist, much coal will be found. A close smothered fire, which has been recommended by some, is very prejudicial.

3. They should be lixiviated with twelve times their weight of boiling water. A drop of the solution of corrosive sublimate will immediately discover when the water ceases to take up any more alkali. The earthy matter that remains is said to be a good manure for clayey soils.

4. The ley thus formed should be evaporated to dryness in iron pans. Two or three at least of these should be used, and the ley, as fast as it is concreted, passed from the one to the other. Thus, much time is saved, as weak leys evaporate more quickly than the stronger. The salt thus produced is of a dark colour, and contains much extractive matter, and, being formed in iron pots, is called potash.

5. This salt should then be carried to a reverberatory furnace, in which the extractive matter is burnt off, and much of the water dissipated: hence it generally loses from ten to fifteen per cent of its weight. Particular care should be taken to prevent its melting, as the extractive matter would not then be perfectly consumed.

The commercial value of this important alkaline body may now be examined. Potash differs considerably from pearl-ash in its value. The best Russian potash, as it is imported into this country, is in large lumps, as hard as a stone, and black as a coal, incrusted over with a white salt, that appears in separate spots here and there in it. It has a strong, fetid, sulphurous smell, as well as a bitter and lixivial taste, which is rather more pungent than other common lixivial salts. A lixivium of it is of a dark green colour, with a sulphurous smell and bitter taste, but more like a simple lixivium. Though it is as hard as a stone when kept in a close place, or in large quantities together in a hogshead, yet, when laid in the open air, it turns soft, and some pieces of it run into a liquid. It readily dissolves in warm water, but leaves a considerable sediment, of a blackish-gray colour, like ashes, which is in a fine soft powder, without any dirt or coals in it, as observed in most other kinds of potash or kelp. As it is dissolving in water, there rise from it some lumps of a dark purple bituminous substance, like petroleum or tar, which readily dissolves in the lixivium.

According to M. Vauquelin, two ounces of various kinds of potash contained as follows:

The pearl-ashes from Russia contained 772 grains of potash, combined with 254 of carbonic acid and water, sixty-five of sulphate of potash, five of common salt, and fifty-six of indissolvable matter.

Dantzic contained 603 grains of potash combined with 304 of carbonic acid and water, 152 of sulphate of potash, fourteen of common salt, and seventy-nine of indissolvable matter.

That from Treves contained 720 grains of potash, combined with 199 of carbonic acid and water, 165 of sulphate of potash, forty-four of common salt, and twenty-four of indissolvable matter.

That from Vosges contained 444 grains of potash in combination with only sixteen of carbonic acid

years; and there are antiquarians who date its production several centuries before the Christian era; since, as has been said, sculpture was declining in excellence in the time of Alexander the Great.

PORTRAITURE. In the article PAINTING we have given a full account of that interesting branch of portraiture which relates to miniature subjects, and the mode of blending colours in oil-painting is adverted to under the same head. The art of delineating the human form is probably as old or older than any other branch of the fine arts. Indeed we are told that the maid of Corinth who traced the outline of her lover, by the shade of a secret lamp, confined herself to delineating his portrait, and this species of outline has since been revived under the name silhouettes. The next step was the monogram, consisting of outlines of figures without light or shade, but with some additions to the parts within the outline. This was speedily followed by ENCAUSTIC PAINTING, described under that article. Portraiture appears to have advanced but very slowly till the time of Apelles, when we find that distinguished artist highly extolled for the accuracy of his likenesses. His portrait of Alexander, placed in the temple of Diana, was considered his masterpiece; and we are told that the mimic lightning he represented appeared about to dart from the picture. Without, however, tracing portraiture through all its stages, it may be enough to say that it attained a high degree of perfection, but to fall in the common wreck of every thing that was refined or valuable in civilized life. In those dark ages which succeeded portraiture made but little progress. It was considered as a very humble branch of the fine arts, and the best painters were engaged in devotional works which required but little skill in accurate portraiture. This remark applies especially to the great recoverers of art, Cimabue, Giotto, Masaccio, Luca, Signorelli, and Leonardo da Vinci. The latter, who was an excellent anatomist, made considerable progress in portraiture.

The terrible sublimity of Michael Angelo has already been illustrated in our history of the fine arts; and his human figures, though they rose from his canvas a race of giants, were still powerful though exaggerated portraits of the human form. Raffaelle humanized portraiture, and threw his own benignant spirit into the features he created. Perfect human beauty he has not represented; but there is a mildness and perfection of keeping in his pictures which raise them very high in the standard of art. The harmony and grace of Correggio was alone wanting to complete the portraiture of the period. But we must hasten by the names of Giulio, Romano, Titian, Caracci, Domenichino, and the other great masters who succeeded to them, and pass at once to the progress of portraiture in our own country.

Holbein and Zuccheri were the earliest portrait painters patronized in this country. The first Charles employed Rubens to paint several large works, and liberally patronized the prince of portrait painters, Vandyke. The English court also gave full employment to the pencils of Sir Peter Lely and Sir Godfrey Kneller. The comparatively humble names of Dobson, Riley, Cooper, Greenhill, Jervas, Richardson, Hayman, and Hogarth, bring us down to a better era.

Sir Joshua Reynolds remodeled the school of portrait painting, which was also much indebted to the accurate delineations of Romney, Opie, and Barry; but it is to the late president of the Royal Academy that we must look for the highest degree of excellence in the art. He created a school from which we are now deriving a degree of benefit without a parallel; and, did our space permit us to speak of contemporary artists, we might point out the good effects of his style as exhibited in the first names of the present day.

We have seen that portraiture commenced with a simple outline, formed by a shadow that was afterwards filled in by a series of tints, which tended to give rotundity and form to the whole. The present mode of effecting this is by the use of a species of lever, of which the axis is movable, and one extremity forms the delineator, while the other is made to pass over the face. Now it will be obvious that, if the arms are equal, the portrait will be the size of the original; but if, on the contrary, the tracing arm be larger than the one which holds the pencil, then the portrait will be but a miniature representation. A nearly similar but still more ingenious apparatus for portraiture has been contrived by Mr. Ronalds. It is described under PERSPECTIVE INSTRUMENTS; and any person possessing that simple apparatus may readily take portraits, with the connecting adjuncts, of any required size, the size being determined by the relative situation of the drawing-paper, and the object to be drawn, from the eye.

The sculptor transfers his portraits from the wax model by a mechanical apparatus very similar to that which we have already described as fitted for the human profile, and dots off on his block of marble the precise points from which the material is to be cut in delineating the portrait.

POTASH. This valuable alkaline body is generally known in commerce under the name of potash, or the vegetable alkali. It is usually procured from the combustion of land vegetables, the process being carried on in those countries which abound in wood. The ashes remaining after the combustion being lixiviated, the liquor affords, on evaporation, saline matter, which, when exposed to heat, forms a solid white mass. This consists of various salts, principally of potash, combined with carbonic acid, partly also of potash combined with sulphuric and muriatic acids, together with silicious earth, oxides of iron and manganese, and occasionally other impurities. The alkaline matter is obtained in different quantities from different vegetables: the harder woods afford more than those that are spongy, shrubs more than trees, herbaceous plants a quantity still larger, and even different parts of the same plant give different proportions of it, the leaves from a given weight yielding more than the branches, and the branches more than the trunk.

Potash is sometimes procured from other sources, and in a state more pure, as from the decomposition by heat of the salt named tartar, or the deflagration of nitre with charcoal, this alkali being the base of these salts. Potash, as obtained by all these processes, is combined with carbonic acid. To abstract this, the saline matter, the subcarbonate of potash, as it is named, is first freed from the other ingredients by lixiviation and evaporation of its solution, and is then mixed with twice its weight of recently slaked lime, and as much water as is necessary to give the consistence of a thin paste: this is put into a glass funnel, the tube of which is obstructed with a piece of linen; the mass of lime soon sub-

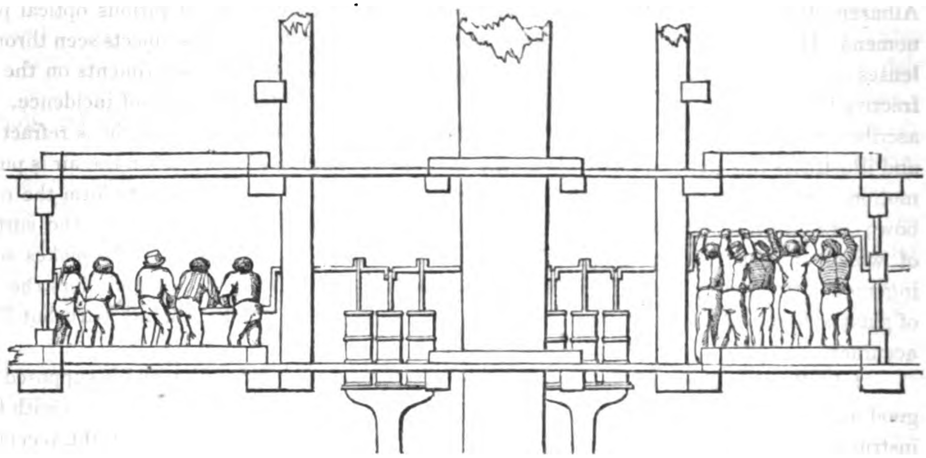
according to circumstances, a position more or less oblique with respect to the course of the stream. From the time of Frontinus to that of Torricelli but little progress was made in our knowledge of the motion of fluids. This eminent mechanic was for some time the contemporary of Galileo. He ascertained the velocity with which water issues from an aperture in the side or bottom of a vessel, and showed that it must be the same velocity which a body would acquire by falling from the level of the surface to the level of the orifice. This proposition, now so well known as the basis of the whole doctrine of hydraulics, was first published by Torricelli at the end of his treatise entitled *De Motu Gravium et Projectorum.*

The beginning of modern experimental improvements in hydraulics may perhaps be dated from the investigations of Smeaton respecting the efforts of wind and water, which were published in the *Philosophical Transactions* for 1759. His observations are of material importance, as far as they are capable of immediate application to practice, but he has done little to illustrate their connection with the general principles of mechanics. M. Borda first derived from a just theory the same results respecting the effects of undershot water-wheels as Smeaton obtained from his experiments about ten years after. Before this time, the best essay on the subject of water-wheels was that by Helvius, published in 1742: his calculations are accurate, but they are founded in a great measure on the imperfect suppositions respecting the impulse of a stream of water which were then generally adopted.

We have already seen that the ancients ascribed the rise of water in pumps to nature's abhorrence of a vacuum, so that the simple operation of the air's pressure was converted into an occult quality. This was the belief even as late as the time of Galileo, who inferred from some of his experiments that nature's abhorrence of a vacuum only extended to between thirty and forty feet. Thus, then, we find that so late as the seventeenth century the science of one of the most distinguished philosophers of the period consisted in transferring from the moral to the physical world the ideas of affection and hatred. The very obvious effect of the pressure of the atmosphere, forcing the water into the vacuous space in the pump-barrel, does not appear to have been understood till the weight of the air had been measured; and the height of the column of water, elevated by a good sucking-pump, is now known to vary with the density of the medium in which it is placed. The force required to work a pump will be as the height to which the water is raised, and as the square of the diameter of the pump-bore in that part where the piston works; so that if two pumps be of equal heights, and one of them be twice as wide in the bore as the other, the wider will raise four times as much water as the narrowest, and will therefore require four times as much strength to work it. The wideness or narrowness of the pump, in any part but that in which the piston works, does not make the pump either more or less difficult to work, except what difference may arise from the friction of the water in the tube, which is always greater in a narrow bore than a wide one, because of the great velocity of the water.

The pump now employed consists, as in the time of Ctesibius, of a barrel furnished with a piston made to fit air-tight. On the elevation of this plug, it will be obvious that a vacuum must be formed beneath; and the perfection of the pump will depend upon the accuracy with which the piston is fitted. The old pumps, by admitting air round the piston, very much impaired their value as hydraulic machines; and in many cases, instead of raising the water between thirty and forty feet, they could scarcely be made to operate till the water had been "fetched" by the assistance of the same fluid poured from above. In other cases the suction-pipe is, even in the present day, frequently so disproportioned to the pump-barrel, that more than a third of the power is lost by the undue velocity given to the ascending column; and even at the present time a pump is exhibited in which cannon balls are raised by this defective construction, the inventor imagining that an advantage may be

obtained by the defect. Some of the best pumps now constructed are those intended for nautical purposes; and the subjoined figure will serve to show the mode of combining power in these hydraulic machines.



The fire-engine is very similar to the double ship's pump, and has been in use, as it is now constructed, for more than a century; but a great improvement has lately been effected by Mr. Braithwaite. He employs a portable steam-engine to give motion to the pump-rod; and, as the steam is prepared during the passage of the fire-engine to its destination, we can hardly conceive a more effective or powerful hydraulic apparatus.

We may now briefly trace the history of *optical science*; and it will be seen that the discoveries connected with this branch of our subject are of a very interesting character. By the agency of optical instruments we are enabled to penetrate the most distant regions of space, and mark the forms and orbits of the planetary bodies; and at the same time, by a slight change in their construction, to bring before the eye of the curious investigator wonders in the animal and vegetable kingdoms which far surpass all that the wildest fictions of Arabian enchantment could devise. By the aid of the magnifying glass, even in its simplest form, we discover that almost every organized body teems with life and motion, and that, when one creature fades before the passage of time and seasonal change, another and frequently a more numerous species of sentient creatures is warmed into action and enjoyment by this apparently destructive process. In fact, we discover that the eye furnishes but the first link in the chain of creative goodness, and that every additional step that we take in the world of microscopic wonders furnishes a new proof of the all-pervading power of that Being whose

— Goodness guides the rushing wind,
And tips the bolt with flame;
Whose wisdom breathes in every breeze,
And warms with every beam.

The first systematic treatise on light is ascribed to Empedocles; and a work on optics, attributed to Euclid, who flourished about 400 years before the Christian era, shows the state of knowledge on the subject generally about that period. The latter work adverts to the effect of bringing into view, by refraction, an object at the bottom of a vessel, by pouring water upon it; but chiefly treats of reflected rays, explaining the effects of different kinds of mirrors, and demonstrating the equality of the angles of incidence and reflection. Ptolemy, in the second century, prepared a treatise on the science of optics generally, though it is

now lost. From this period but little occurs worthy of notice, till Alhazen, an Arabian author, in the eleventh century, gave an account of the magnifying power of lenses; and in 1270 Vitellio, a Pole, wrote a treatise on this science, containing all that was valuable in Alhazen, digested in a better manner, and with clearer explanations of various optical phenomena. He observes that light is always lost by refraction, which makes objects seen through lenses appear less luminous. He gave a table of the results of his experiments on the refractive powers of air, water, and glass, corresponding to the different angles of incidence. He ascribes the twinkling of the stars to the motion of the air in which the light is refracted; and illustrates this hypothesis by observing that they twinkle still more when the air is put in motion. He also asserts that refraction is necessary, as well as reflection, to form the rainbow; because the body which the rays fall upon is a transparent substance, at the surface of which one part of the light is always reflected and another refracted. He makes some ingenious attempts to explain refraction, or to ascertain the law of it; and considers the foci of glass spheres, and the apparent size of objects seen through them, though with but little accuracy.

John Baptista Porta of Naples was a very ingenious experimentalist, and is supposed, on good authority, to have been the inventor of the camera obscura. His experiments with that instrument induced him to believe that light must certainly be a substance, by the reception of which into the eye vision was accomplished. The importance of this suggestion will be evident when it is observed that previous to his time vision was supposed to be dependent upon what were termed visual rays proceeding from the eye. He justly considered the eye itself as a natural camera obscura, the pupil performing the office of the hole in the window-shutter: he remarked also that a defect of light is remedied by the dilatation of the pupil, which contracts involuntarily when exposed to a strong light, and expands when the light is too faint for distinct vision. Baptista Porta, by publishing an account of the magic lantern, tended very materially to diffuse a taste for scientific pursuits, as he was enabled with that ingenious instrument to amuse as well as to instruct his pupils.

The commencement of the seventeenth century is justly celebrated for the application of the telescope to astronomical purposes, and for this instrument we are most especially indebted to Galileo. Other accounts transfer the merit of the first discovery to Jansen, whose children, while amusing themselves with a series of spectacle-glasses in his shop, perceived that when they held two of these lenses between their fingers, at a certain distance from each other, the dial of the clock appeared greatly magnified, but in an inverted position. This incident suggested to their father the idea of adjusting two glasses on a board so as to move them at pleasure to any required distance. To the Jansens we are also indebted for the discovery of the microscope, an instrument depending upon exactly the same principles as the telescopic tube. In fact, it is not improbable that the double lens was first applied to the observation of near but minute objects, and afterwards on the same principles to objects which appeared minute on account of their distance. The discovery of the different refrangibility of the component rays of light suggested defects in the construction of telescopes which were before unthought of; and, in the creative hands of a Newton or a Dollond, led to some no less extraordinary improvements in them.*

* A very beautiful analogy between the microscope and this instrument has been drawn by Dr. Chalmers. He says, speaking of the two instruments, "The one led me to see a system in every star; the other leads me to see a world in every atom. The one taught me that this mighty globe, with the whole burden of its people and of its countries, is but a grain of sand on the high field of immensity; the other teaches me that every grain of sand may harbour within it the tribes and the families of a busy population. The one told me of the insignificance of the world I tread upon; the other redeems it from all its insignificance, for it tells me that in the leaves of every forest, and in the flowers of every garden, and in the waters of every rivulet, there are worlds

To proceed, however, in our historical view of the science of optics, it may be proper to state that it was Kepler who first clearly explained the effects of lenses in making the rays of a pencil of light converge or diverge. He showed that a plano-convex lens makes rays that were parallel to its axis to meet at the distance of the diameter of the sphere of convexity; but that, if both sides of the lens be equally convex, the rays will have their focus at the distance of the radius of the circle corresponding to that degree of convexity. But he did not investigate any rule for the foci of lenses unequally convex. He only says, in general, that they will fall somewhere in the medium between the foci belonging to the two different degrees of convexity. It is to Cavallieri that we owe this investigation. He laid down the following rule:—As the sum of both the diameters is to one of them, so is the other to the distance of the focus. All these rules concerning convex lenses are applicable to those that are concave; with this differcnce, that the focus is on the contrary side of the glass.

It is generally admitted that we are indebted to Kepler for the first development of the theory of the astronomical telescope. The *rationale* of this instrument is explained, and the advantages of it are clearly pointed out, by this philosopher, in his *Catoptrics;* but, what is very surprising, he never reduced his excellent theory into practice. Montucla conjectures that the reason why he did not make trial of his new instrument was his not being aware of the great increase of the field of view, so that, being engaged in other pursuits, he might not think it of much consequence to take any pains about the construction of an instrument which could do little more than answer the same purpose with those of which he was already possessed. He must also have foreseen that the length of this telescope must have been greater in proportion to its magnifying power, so that it might appear to him, upon the whole, not quite so good a construction as the former. It was not long, however, before Kepler's suggestion was acted on: Scheiner constructed an instrument on this principle, and published a description of it, in 1630. "If," says he, "you insert two similar lenses (that is, both convex) in a tube, and place your eye at a convenient distance, you will see all terrestrial objects inverted, indeed, but magnified and very distinct, with a considerable extent of view." He afterwards subjoins an account of a telescope of a different construction, with two convex eye-glasses, which again reverses the images, and makes them appear in their natural position. This disposition of the lenses had also been pointed out by Kepler, but had not been reduced to practice by him any more than the former. This construction, however, answered the end but very imperfectly; and father Rheita was the first who suggested the employment of three glasses, instead of two. This acquired the name of the *terrestrial telescope*, being chiefly used for viewing terrestrial objects. The invention of the telescope and microscope having incited mathematicians to a more careful study of dioptrics, and this having soon become a perfect science, by means of the discoveries of Snellius, many different constructions were offered to the public. Huyghens was particularly eminent for his systematic knowledge of the subject, and was the author of some of the chief improvements which were made on dioptrical instruments till the time of Dollond's great discovery. He was well acquainted with the theory of aberration arising from the

---

teeming with life, and numberless as are the glories of the firmament. The one has suggested to me that beyond and above all that is visible to man there may be fields of creation which sweep immeasurably along and carry the impress of the Almighty's hand to the remotest scenes of the universe; the other suggests to me that within and beneath all that minuteness which the aided eye of man has been able to explore there may be a region of invisibles, and that, could we draw aside the mysterious curtain which shrouds it from our senses, we might there see a theatre of as many wonders as astronomy has unfolded—a universe within the compass of a point so small as to elude all the powers of the microscope, but where the wonder-working God finds room for the exercise of all his attributes, where he can raise another mechanism of worlds, and fill and animate them with all the evidences of his glory."

spherical figure of the glasses, and has pointed out several ingenious methods of diminishing them by proper constructions of the eye-pieces. He first showed the advantages of two eye-glasses on the astronomical telescope and double microscope, and gave rules for their construction, which both enlarges the field and shortens the instrument.

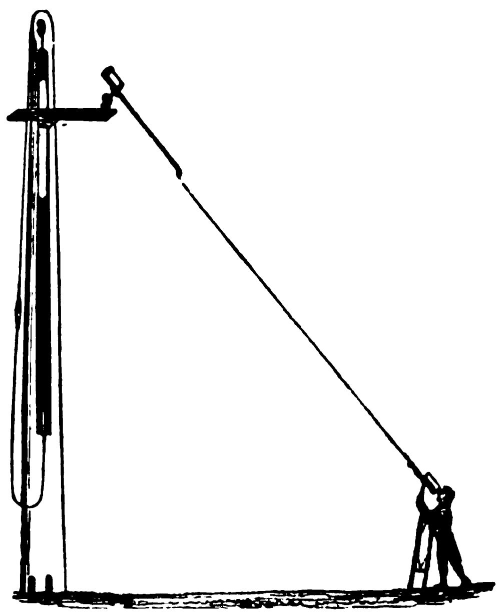
Des Cartes published a large work on optics in 1637, and from that period a considerable interval took place, during which optics, and indeed science in general, made but little progress, till the *Optica Promota* of James Gregory, in 1663, seemed to put them again in motion. The author of this work, a profound and inventive geometer, had applied diligently to the study of optics, and the improvement of optical instruments. The *Optica Promota* embraced several new enquiries concerning the illumination and distinctness of the images formed in the foci of lenses, and contained an account of the reflecting telescope, still known by the name of its author. The consideration which suggested this instrument was the imperfection of the images formed by spherical lenses, in consequence of which they are not in plane, but in curved surfaces. The desire of removing this imperfection led Gregory to substitute reflection for refraction in the construction of telescopes; and by this means, while he was seeking to remedy a small evil, he provided the means of avoiding a much greater one, with which he was yet unacquainted, viz. that which arises from the unequal refrangibility of light. The attention of Newton was about the same time drawn to the same subject, but with a perfect knowledge of the defect which he wanted to remove. Gregory thought it necessary that the specula should be of a parabolic figure; and the execution proved so difficult that the instrument, during his life, was never brought to any perfection. The specula were afterwards constructed of the ordinary spherical form; and the Gregorian telescope, till the time of Herschel, was more in use than the Newtonian.

Newton, in some of his earliest experimental investigations, applied himself to the improvement of the telescope; but, imagining that Gregory's speculum was neither very necessary nor likely to be executed, he began with prosecuting the views of Des Cartes, who aimed at making a more perfect image of an object by grinding lenses, not to the figure of a sphere, but to that of one of the conic sections. Whilst he was thus employed, three years after Gregory's publication, he had his attention particularly directed to the colours formed by a prism, and, having by means of that simple instrument discovered the different refrangibility of the rays of light, he then perceived that the errors of telescopes arising from that cause alone were some hundred times greater than such as were occasioned by the spherical figure of the lenses. This circumstance forced, as it were, Newton to fall into Gregory's track, and to turn his thoughts to reflectors. "The different refrangibility of the rays of light," says he, in a letter to Mr. Oldenburg, secretary of the Royal Society, "made me take reflectors into consideration, and finding them regular, so that the angle of reflection of all sorts of rays was equal to the angle of incidence, I understood that by their mediation optical instruments might be brought to any degree of perfection imaginable, provided a reflecting substance could be found which would polish as finely as glass, and reflect as much light as glass transmits, and the art of communicating to it a parabolic figure be also obtained. Amidst these thoughts I was forced from Cambridge by the intervening plague, and it was more than two years before I proceeded further."

Optics, as well as all the other branches of natural philosophy, have great obligations to Huyghens. The former was among the first scientific objects which occupied his mind; and his *Treatise on Optics*, though a posthumous work, is most of it the composition of his early youth. It is written with great perspicuity and precision, and is said to have been a favourite book with Newton himself. Though beginning from the first elements, it contains a full development of the matters of greatest difficulty in the construction of telescopes, particularly in what concerns the indistinctness arising from the imperfect foci into which rays are

united by spherical lenses; and rules are deduced for constructing telescopes which, though of different sizes, shall have the same degree of distinctness, illumination, &c. Huyghens was, besides, a practical optician: he polished lenses and constructed telescopes with his own hands, and some of his object-glasses were of the enormous focal distance of 130 feet.

It is generally supposed that the great reflecting telescopes employed in modern times have a greater focal length than any which had preceded them. This, however, is not the fact, as refracting telescopes of much greater length had really been attempted to be employed by M. Auzot in France in the seventeenth century. The enormous instruments made by Huyghens and others at the same period were employed without a tube. Huyghens placed his object-glass in a tube at the top of a long pole; the axis of this tube he could command with a silk string, so as to bring it into a line with the axis of another short tube which he held in his hand, and which contained the eye-glass. In the subjoined engraving we have attempted to delineate one of these extraordinary instruments, which for cheapness far surpasses any thing of the kind now used. It will, however, be sufficiently obvious that the important discoveries made with the Herschellian telescope could never have been effected by this instrument.



Prior to the invention of the achromatic glass it was generally supposed that the objects viewed through the telescope must in every form of the instrument be coloured, though some vague hopes, grounded chiefly on the consideration of final causes, were still at times entertained of removing that defect. As the eye consists of two distinct humours, with a horny lens or cornea interposed, it was naturally imagined that such a perfect structure should be imitated in the composition of glasses. This inviting idea is concisely mentioned by David Gregory, the nephew of James, in his little tract on dioptrics. It has also been stated that a country gentleman, Mr. Hall of Chesterhall, in Worcestershire, discovered, about the year 1729, the proper composition of lenses by the united segments of crown and flint-glass, and caused a London artist in 1733 to make a telescope under his directions, which was found on trial to answer extremely well. But, whatever might be the fact, no notice was taken of it at the time, nor indeed till very long after, when circumstances had occurred to call public attention to the subject.

The Newtonian principle was first publicly examined, and a discussion excited which eventually led to a most valuable discovery in optics by a foreign mathematician of great celebrity and transcendant talents. Leonard Euler was a very distinguished mathematician, and especially directed his attention to the subject of optics. Endowed with a penetrating genius and profound capacity, he was capable of pursuing his abstruse investigations with unremitting ardour and unwearied perseverance. To him the modern analysis stands chiefly indebted for its prodigious extension, and he continued to enrich it in all its departments with innumerable improvements and fine discoveries during the whole course of a most active, laborious, and protracted life. Unfortunately the philosophical character of Euler did not correspond to his superlative eminence as a geometer. Bred in the school of Leibnitz, he had

imbibed the specious but delusive metaphysics of the *sufficient reason*, and of the necessary and absolute constitution of the laws of nature. He was hence disposed in all cases to prefer the mode of investigating *à priori*, and never appeared to hold in due estimation the humbler yet only safe road to the knowledge of physical science, by the method of experiment and induction. In the *Berlin Memoirs* for 1747 he inserted a short paper, in which he deducted from optical principles by a clear analytical process, conducted with his usual skill, the composition of a lens formed after certain proportions with glass and water, which should remove entirely all extraneous colours, whether caused by the unequal refraction of the several rays or by spherical aberration; and, in concluding, he remarked, with high satisfaction, the general conformity of his results with the wonderful structure of the eye.

But this paper met with opposition in a quarter where it could have been least expected. John Dollond, who had afterwards the honour of completing one of the finest and most valuable discoveries in the science of optics, was born in 1706, in Spitalfields, of French parents, whom the edict of Nantes had compelled to take refuge in England from the cruel persecution of an ignorant and bigoted tyrant. Following his father's occupation, that of a weaver, he married at an early age; and being fond of reading he dedicated his leisure moments to the acquisition of knowledge. By dint of solitary application, he made some progress in the learned languages; but he mainly devoted his attention to the study of geometry and algebra, and the more attractive parts of mixed or practical mathematics. He gave instructions in these branches to his son Peter, who, though bred to the hereditary profession, soon quitted that employment, and commenced the business of optician, in which he was afterwards joined by his father. About this time the volume of the *Berlin Memoirs*, containing Euler's papers, fell into the hands of the elder Dollond, who examined it with care, and repeated the calculations. The result of his examination was communicated by Mr. Short to the Royal Society in 1752, and published in their *Transactions* for that year. Dollond, as might well be expected, could detect no mistake in the investigation itself, but strenuously contested the principle on which it was built, as differing from the one laid down by Newton, which he held to be irrefragable. "It is, therefore," says he, rather uncourteously, and certainly with little of the prophetic spirit, "it is therefore somewhat strange that any body now-a-days should attempt to do that which so long ago has been demonstrated impossible." The great Euler replied with becoming temper, but persisted in maintaining that his optical principle was a true and necessary law of nature, though he frankly confessed that he had not been able to reduce it yet to practice. Unsatisfied by the arguments of Euler, the humble and unassisted optician applied himself closely to experimental investigation, and, having proved the power of an achromatic arrangement of prisms, next tried so to adapt the opposite refractions as to destroy all extraneous colour. This effect he found to take place when the angle of the wedge had been further increased till the refracting power of the water was to that of the glass in the ratio of five to four. His conclusive experiments were made in 1757, and he lost no time in applying their results to the improvement of the object-glasses of telescopes. Following the proportion just ascertained, he conjoined a very deep convex lens of water with a concave one of glass. In this way he succeeded in removing the colours occasioned by the unequal refraction of light; but the images formed in the foci of the telescopes so constructed still wanted the distinctness which might have been expected. The defect now proceeded, it was evident, from spherical aberration; for, the excess of refraction in the compound lens being very small, the surfaces were necessarily formed to a very deep curvature. But this partial success only stimulated the ingenious artist to make further trials. Having proved that the separation of the extreme rays, or what has been since termed the *dispersive power*, is not proportioned to the mean refraction in the case of glass and water, he might fairly presume that like discrepancies must exist among other diaphanous substances,

and even among the different kinds of glass itself. Having made this discovery, which at once furnished him with the materials for his achromatic arrangement, Mr. Dollond was encouraged to proceed, with the confident hope of ultimately achieving his purpose. His new researches, however, were postponed for some time by the pressure of business. But, on resuming the enquiry, he found the English crown-glass and the foreign yellow or straw-coloured, commonly called the Venice-glass, to disperse the extreme rays almost alike, while the crystal, or white flint-glass, gave a much greater measure of dispersion. A wedge of crown and another of flint-glass were afterwards ground till they refracted equally, which took place when their angles were respectively 29° and 25°, or the indices of refraction were nearly as 22 to 19; but, on being joined in an inverted position, they produced, without changing the general direction of the pencil, a very different divergence of the compound rays of light. He now reversed the experiment, and formed wedges of crown and flint-glass to such angles as might destroy all irregularity of colour by their opposite dispersions.

In 1758 the labours of Mr. Dollond were rewarded with complete success. "Notwithstanding," says he, in concluding his paper, "so many difficulties as I have enumerated, I have, after numerous trials, and a resolute perseverance, brought the matter at last to such an issue that I can construct refracting telescopes with such apertures and magnifying powers, under limited lengths, as, in the opinion of the best and undeniable judges, who have experienced them, far exceed any thing that has been produced, as representing objects with great distinctness, and in their true colours." The Royal Society voted to Mr. Dollond, for his valuable discovery, the honour of the Copley medal. To this new construction of the telescope, Dr. Bevis gave the name of *achromatic*, which was soon universally adopted, and is still retained. The inventor took out a patent, but did not live to reap the fruits of his ingenious labours. He died in the year 1761, leaving the prosecution of the business to his son and associate, Peter Dollond, who realized a very large fortune by the exclusive manufacture, for many years, of achromatic glasses, less secured to him by the invidious and disputed provisions of legal monopoly than by superior skill, experience, and sedulous attention. In 1765, the younger Dollond made another and final improvement, to which his father had before advanced some steps. To correct more effectually the spherical aberration, he formed the object-glass of three instead of two lenses, by dividing the convex piece; or he enclosed a concave lens of flint-glass between two convex lenses of crown-glass.

Mr. Tulley has succeeded in applying the achromatic principle of Dollond to the smallest sized glasses, and the improvements effected by Guinaud and Faraday, in the manufacture of glass, have given to this portion of the telescope a degree of excellence which could hardly have been contemplated by the opticians to whose labours we have had occasion to allude. Aided by instruments of this description, astronomers have been able to observe not only stars, planets, and satellites, invisible to the naked eye, but to measure the height of mountains in our own satellite, and discover volcanoes, or burning mountains, on its surface.

We are mainly indebted to the late Sir William Herschel for the improvements that have been made in the reflecting telescope. In 1781, Sir William Herschel began a thirty-feet aërial reflector; but his mirror, thirty-six inches in diameter, having at one time cracked in the cooling, and at another period run into the fire, from a failure in the furnace, his object was partially abandoned. But, the plan for forming a telescope of extraordinary size having been submitted by Sir Joseph Banks to the king, his majesty offered to defray the expense of it, and, under his patronage, this distinguished optician began, about the end of the year 1785, to construct a telescope of forty feet in focal length. This splendid instrument, which magnified 6450 times, was completed on the 27th of August, 1789; and on the day following Herschel discovered a new satellite belonging to the planet Saturn.

In the article MICROSCOPE we have fully traced the various improvements that have been effected in that instrument from the time of Leuenhoek to the present period; and we may content ourselves with remarking that the microscope, as it is now constructed, amazingly extends the boundaries of the organs of vision, enables us to examine the structure of plants and animals, presents to the eye myriads of beings of whose existence we had before formed no idea, and furnishes the philosopher with an exhaustless field of investigation. "It leads," to use the words of an ingenious writer, "to the discovery of a thousand wonders in the works of his hand who created ourselves, as well as the objects of our admiration; it improves the faculties, exalts the comprehension, and multiplies the inlets to happiness; it is a new source of praise to him to whom all we pay is nothing of what we owe; and, while it pleases the imagination with the unbounded treasures it offers to the view, it tends to make the whole life one continued act of admiration." The oxy-hydrogen microscope is peculiarly fitted to explain, on a large scale, the wonders of the animal and vegetable kingdoms: and its simplicity is such that any person who has a sufficient practical acquaintance with chemistry to produce the steady white light which results from the combustion of the oxy-hydrogen gases on lime may employ the apparatus.

The micrometer is an important part both of the telescopic and microscopic apparatus, and as such must not be passed unnoticed. By the aid of a micrometer we may either measure the size of a planetary body or the smallest object of microscopic investigation. But little use was made of the micrometer for telescopic purposes till the time of Mr. Ramsden, who invented two instruments of this description. Sir William Herschel, also, invented a lamp micrometer, which he employed with one of his powerful telescopes. Cavallo's micrometer is simple and valuable. It consists of a small semi-transparent scale, or slip of mother-of-pearl, about the twentieth part of an inch broad, and of the thickness of common writing-paper. It is divided into a number of equal parts, by means of parallel lines, every fifth and tenth division of which is a little longer than the rest. This micrometer, or divided scale, is situated within the tube, at the focus of the eye-lens of the telescope, where the image of the object is formed, and with its divided edge passing through the centre of the field of view, though this is not absolutely necessary. It is immaterial whether the telescope be a refractor or a reflector, provided the eye-lens be convex, and not concave, as in the Galilean telescope.

The mother-of-pearl micrometer may be applied to a microscope, and it will thus serve to measure the lineal dimensions of an object. In some of the best forms of the micrometer, the eye-tube through which the object is viewed is divided by threads or filaments, and scientific men have often had occasion to regret the difficulty of procuring fibres sufficiently elastic for micrometers. The difficulty of obtaining silver wire of a diameter small enough induced Mr. Troughton to use the spider's web, which he found so fine, opaque, and elastic, as to answer all the purposes of practical astronomy. But, as it is only the stretcher, or long line which supports the web, that possesses these valuable properties, the difficulty of procuring it has compelled many opticians and practical astronomers to employ the raw fibres of unwrought silk, or, what is still worse, the coarse silver wire manufactured in this country. For these Sir David Brewster has succeeded in obtaining a substitute in a delicate fibre, which enables the observer to remove the errors of inflection, while it possesses the requisite property of opacity and elasticity. This fibre is made of glass, which is so exceedingly elastic that it may be drawn to any degree of fineness, and which can always be procured and prepared with facility. This vitreous fibre, when drawn from a hollow tube, will always be of a tubular structure, and its interior diameter may always be regulated by that of the original tube. When such a fibre is formed, and stretched across the diaphragm of the eye-piece of a telescope, it will appear perfectly opaque, with a delicate line of light

extending along its axis. As this central transparency arises from the transmission of the incident light through the axis of the hollow tube, and this tube can be made of any calibre. the diameter of the luminous streak can either be increased or diminished. In a micrometer fitted up in this way by Sir David Brewster, the glass fibres are about 1-1200th part of an inch in diameter; and the fringe of light is distinctly visible, though it does not exceed 1-3000th part of an inch. The inventive genius of Dr. Wollaston has, however, far outstripped those who preceded him in the production of a micrometer fibre. The contrivance by which it is effected is so ingenious, and promises to be productive of such beneficial results, that it may be advisable to annex the account of the process employed by this philosopher.—"The extremity of a platinum wire, having been fused into a globule nearly one-fourth of an inch in diameter, was next hammered out into a square rod, and then drawn again into a wire 1-253rd of an inch in diameter. One inch of this wire, duly coated with silver, was drawn till its length was extended to 182 inches. The silver was then destroyed by the action of a corrosive acid, leaving the exquisitely minute core of platinum for the micrometer fibre."

The nature of light must now more particularly engage our attention. There are two theories, or rather hypotheses, that have been adopted to explain the action of light with reference to its transmission: the one supposes the ray to consist of small particles, and as such material; while the other presumes the existence of a fluid, pervading all space, which, by its vibratory motion, enables us to see luminous bodies. According to the latter hypothesis light may be considered as analogous to sound, which is known to depend entirely upon the pulsations of the air and other sonorous bodies transmitting a vibratory motion to the organs of hearing. A very striking circumstance respecting the propagation of light is the uniformity of its velocity in the same medium. According to the projectile hypothesis, the force employed in the free emission of light must be enormously greater than the force of gravity at the earth's surface, and it must either act with equal intensity on all the particles of light, or must impel some of them through a greater space than others if its action be less powerful, since the velocity is the same in all cases; for example, if the projectile force is weaker with respect to red light than with respect to violet light, it must continue its action on the red rays to a greater distance than on the violet rays. There is no instance in nature besides of a simple projectile moving with a velocity uniform in all cases whatever may be its cause; and it is extremely difficult to imagine that so immense a force of repulsion can reside in all substances capable of becoming luminous, so that the light of decaying wood, or of two pebbles rubbed together, may be projected precisely with the same velocity as the light emitted during the combustion of iron in oxygen gas, or by the reservoir of liquid fire on the surface of the sun. Another cause would also naturally interfere with the uniformity of the velocity of light if it consisted merely in the motion of the projected corpuscles of matter. M. Laplace has calculated that, if any of the stars were 250 times as great in diameter as the sun, their attraction would be so strong as to destroy the whole momentum of the corpuscles of light proceeding from it, and to render the star invisible at a great distance; and, although there is at present no reason to imagine that any of the stars are actually of this magnitude, yet some of them are probably many times greater than our sun, and therefore large enough to produce such a retardation in the motion of its light as would materially alter its effects.

If, however, we adopt the opinion that the particles of light are material, and that they are continually passing from the various luminous bodies that surround us, it may be enquired why do they not interfere with each other in such a manner as to confound all perception of objects, if not quite destroy the sense of seeing? Their velocity, however, enables us to answer these questions, by convincing us that they may be separated at least 1000 miles, and

yet be perfectly efficient for the purposes of vision. It is an undoubted fact that the effect of light upon the eye is not instantaneous, but that the impression remains after the light has been withdrawn. Of this any one may satisfy himself by shutting his eye after having looked for some time on a candle, a star, or any other luminous object, when a faint momentary picture of the object will remain. The same thing may be proved by whirling round a stick, the extremity of which is on fire, if the motion be quick enough the perception of a complete circle of flame will be impressed upon the eye. The actual duration, for a certain time, of the impression of light being thus proved, let it be supposed to continue distinct only for the 150th part of a second; then, if one lucid point of the sun's surface emit 150 particles of light in a second, these will be amply sufficient to afford light to the eye without any intermission, and yet the particles emitted will be more than 1000 miles apart. It has been ascertained by the astronomical observations of Roemur and Bradley that each ray of light emitted by the sun arrives at the earth in eight minutes and one-eighth when the earth is at the mean distance of about 95,000,000 miles. Roemur deduced this velocity from observations on the eclipses of the satellites of Jupiter; and Bradley confirmed it by his discovery of the cause of the apparent aberration of the fixed stars. But we have other proofs not less decisive than this of the extreme minuteness of the particles of light, when we observe with what facility they penetrate the hardest bodies, as glass, crystal, precious stones, and even the diamond itself, through all which they find an easy passage, or those bodies could not be transparent. When a candle is lighted, if there is no obstacle to obstruct its rays, it will fill a space of two miles round with luminous particles in an instant of time, and before the least sensible part is lost by the luminous body. Nay, how small must the particles of light be, when they pass without removing the minutest particles of microscopic dust that lie in their way, and even these minute particles are rendered visible by reflecting back the particles of light that strike against them. Some bodies intercept light, or are opaque; others allow its transmission, and as such are transparent; and there are gradations from perfect opacity to perfect transparency. It is probable that opacity results from the attraction of the substance for light, and not from its density; for it can scarcely be supposed that the particles of bodies should not be far enough distant to allow of the passage of light. Newton supposes the particles of transparent bodies to be of uniform density and arrangement, and, attracting the rays of light equally in every direction, they suffer it to pass through them without obstruction; whereas, in opaque bodies, the particles are either of unequal density or irregularly arranged, and the light, being unequally attracted, cannot therefore penetrate the body.

Experience has long since established the fact that vegetables become destitute of smell and colour, and lose much of their combustibility, by growing in the dark. In Dr. Black's *Lectures* we find an illustration of this circumstance given by the celebrated Dr. Robinson, of Edinburgh. In the drain of a coal-work, under ground, he accidentally laid his hand upon a very luxuriant plant, with large indented foliage, and perfectly white. He had not seen any thing like it, nor could any one inform him what it was. He had the plant brought into the open air in the light. In a little time the leaves withered, and soon after new leaves began to spring up, of a green colour and of a different shape from that of the old ones. On rubbing one of the leaves between his fingers, he found that it had the smell of common tansy, and ultimately it proved to be that plant, which had been so changed by growing in the dark. Indeed, it was recollected that some rubbish had been taken down into the drain from a neighbouring garden, some time before it was found so altered. This effect of light is not less conspicuous in the growth of celery. By covering it with earth, the light is shut out, which would very soon turn it green, and render its flavour so strong as to make it unfit to be eaten, at the same time that it would render it more fibrous.

e 2

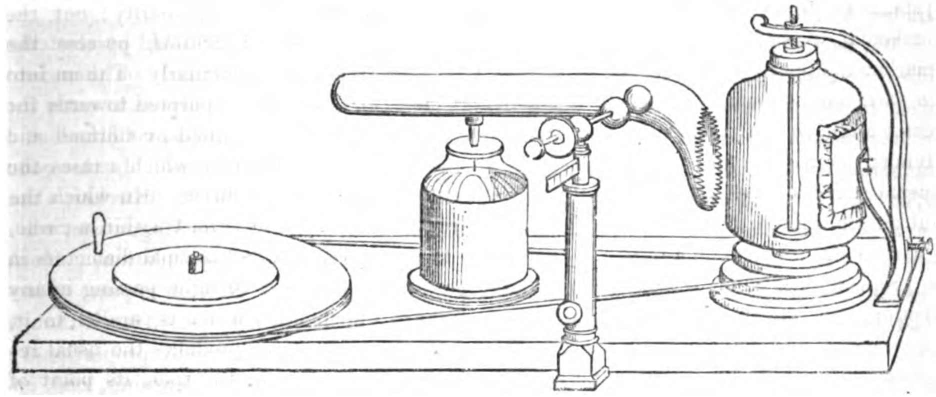
We have seen that light is refracted in passing from one medium to another, and that this property is employed in the formation of lenses for optical instruments. Familiar examples of the effects of natural refraction may be adduced by the bending of the image of a rod placed obliquely in water, or the exquisitely painted spectrum depicted in the heavens by the drops of falling rain. These paradoxical effects were observed at an early period; but the most singular of all the phenomena of refraction is, perhaps, the property of some natural substances, which have a double effect on the light transmitted through them, as of two mediums of different densities, freely pervading each other, the one only acting on some of the rays of light, the other on the remaining portion. These substances are usually crystallized stones, and their refractions have sometimes no further peculiarity; but the rhomboidal crystals of calcareous spar, commonly called *Iceland crystal*, possess the remarkable property of separating such pencils of light as fall perpendicularly on them into two parts, one of them only being in the usual manner, the other being deflected towards the greater angle of the crystal. It appears from the experiments of Huyghens, confirmed and extended by Dr. Wollaston and Sir David Brewster, that the medium which causes the unusual refraction has a different refractive power, according to the direction in which the light passes through it; and if an oblate or flattened spheroid be described within a circle, its axis being in the middle of one of the obtuse solid angles, and its principal diameters in the proportion of nine to ten, the refractive power, with respect to light passing in any direction, will always be inversely as the diameter of the spheroid which is parallel to it, and where it is greatest will be equal to that of the medium which produces the usual refraction. A ray of light falling perpendicularly on any surface of the spar, its point of incidence being considered as the centre of the spheroid, will meet the surface of the spheroid at the point where it is parallel to that of the spar; and a ray incident on the same surface in any other direction will preserve a relation to the perpendicular ray which is nearly the same as in ordinary refraction.

There is a considerable analogy subsisting between some of the phenomena of light, electricity, and magnetism. *Electricity* appears to pervade the whole of created nature, and yet our acquaintance with some of its most simple phenomena can scarcely be traced further than the middle of the last century. We have already had occasion to advert to the experimental labours of Grey, a pensioner of the charter-house. He was followed in the march of discovery by Dufay, who, in 1733, described the existence of two opposite species or kinds of electricity. These he called the *vitreous* and the *resinous*, the former being excited by rubbing glass, and the latter by the friction of amber, resin, &c. He also gave a clear view of the phenomena of electrical attraction and repulsion, by demonstrating that bodies similarly electrified mutually repel, while those dissimilarly electrified attract each other. We have exhibited, at page vi., the simple electrical apparatus employed by these early experimentalists; and Francis Hawksbee appears to have been the first to employ a globe of glass to collect the electric fluid. One or more gun-barrels, suspended horizontally by silk cords, were furnished with small bundles of linen threads, and the curious found amusement in drawing sparks, and firing inflammable substances. After this electricity became a favourite remedy with the empirics; and in 1745 a very important discovery was made at Leyden, where Messrs. Cuneus and Lallemand, in attempting to electrify some water contained in a glass vessel, received a severe shock. By this singular discovery, a power was obtained incomparably greater than that of the mere spark.*

---

* The shock or convulsive agitation accompanying the discharge of a loaded jar through the nervous system at first inspired terror, and still continues to excite surprise and astonishment. The swiftness of electrical communication thus displayed seemed to exceed the rapidity of thought itself. Nollet, a popular lecturer on experimental philosophy at Paris, sent the shock, with instantaneous effect, through a whole

The analogy which subsists between electricity produced by artificial means and that which results from the passage of an electrical cloud appears to have been first satisfactorily pointed out by Dr. Benjamin Franklin. His experiments also led to the formation of an hypothesis intended to illustrate the existence of electricity in a positive and negative state, so that, when the Leyden jar has its electrical equilibrium destroyed by communication with the electrical machine, the one side of the jar is plus and the other minus. The apparatus employed for exhibiting these and other experiments now assumed a new and improved character. The stick of glass was replaced by a glass globe, or cylinder, whirled round by a large wheel and cord, such as is shown in the subjoined wood-cut.



Dr. Franklin, continuing his experimental researches, was enabled, by the agency of a kite raised to a considerable height, to bring down the electric fluid naturally from the atmosphere. The success of this trial encouraged him to entertain the bold project of turning aside the stroke of the thunderbolt, and of guarding our edifices from the flash of the forked lightning, by the erection of lofty conductors.

The power of benumbing the touch, which belongs to a certain fish of the ray kind, thence called the torpedo, and very frequent in the Mediterranean, had been remarked from the earliest times. This singular property was now suspected to be owing to electrical influence; and the zeal of Walsh, in 1733, converted the conjecture into demonstration, showing, by satisfactory experiments, that the animal could send its shock only through conducting substances. But the power of stunning its prey is possessed in a much higher degree by the *silurus electricus*, which was originally brought from Surinam, and abounds in the pools and sluggish streams in the hot region of Venezuela. From a healthy specimen exhibited in London vivid sparks were drawn in a darkened room.

The discoveries of Galvani and Volta formed a new era in the progress of this science. Galvani, professor of anatomy at Bologna, remarked, in the course of his demonstrations, that the limbs of a dissected frog were strongly convulsed at every spark which one of his pupils happened to draw from the prime conductor of an electrical machine standing in the immediate vicinity. Being thus led to consider the subject, he made several curious experiments, and published a *Dissertation on Animal Electricity*, which engaged very general attention. The femoral muscles of a frog, bared of their integuments, but left connected with the trunk of nerves, were found to serve as a most delicate sort of electrometer. With

---

regiment of guards; and Watson, an ingenious physician in London, could discover no interval of time in its transmission through a circuit of about six miles. Helvig, however, seems to have measured its velocity by the aid of a camera lucida, and Mr. Wheatstone has lately contrived an instrument which registers the precise time that it occupies to pass over a given distance.

this aid it was easy to trace the faintest vestiges of electrical influence, and to contrast the properties of various conductors. The very weakest chemical solutions, the mere contact of different metals, nay, the apposition of animal fibres, were all found in their several degrees to develope electricity. But the simplest mode of exciting it now known is by the mutual application of small disks of copper and zinc. Volta, in 1800, invented the *pile*, which still bears his name, the most energetic instrument of all electro-chemical analysis, and commencing deservedly a new epoch in physical science. By Cruikshanks it was rendered far more commodious, in being converted into the Galvanic trough, which again enlarged into batteries, sometimes of enormous extent or dimensions, has conducted Davy, Berzelius, Faraday, &c., to the most splendid and wonderful discoveries.

We have seen that there are peculiar attractions and repulsions exhibited by electrified bodies; now nearly similar phenomena occur with those that are magnetized. The ancients appear to have known but little of *magnetism*. It is not our present purpose to enter into the long-disputed question as to whether the compass was really invented by Columbus, or whether, as some suppose, the honour of its discovery belongs to the Chinese. In this country, at least, but little was known of the matter till the time of Dr. Gilbert. Kircher, a man of extraordinary talent and erudition, produced at Cologne a full treatise on Magnetism, which contained little however of sound doctrine, but abundance of fanciful speculation. Hooke remarked the injurious effect of heat on the power of the magnet. Newton appears to have sometimes amused himself with magnetic experiments, but he did not bestow much thought on the subject: he was disposed to consider the force exerted as reciprocally proportional to the cube of the distance. The celebrated Halley, who by his ingenuity, learning, zeal, and enterprise, contributed so largely to the promotion of physical science, now turned his attention to the subject of terrestrial magnetism. In 1683, and more distinctly in 1692, he endeavoured to explain the declination of the needle and its variations, by supposing the earth to be a hollow sphere, containing a magnet of analogous polarity, which revolved slowly within it. From this bold hypothesis, of two fixed, combined with two movable poles, he sought to calculate the changes of internal constitution that are continually going forward. Coulomb was enabled by the aid of his balance of Torsion to discover the true law of magnetic attraction and repulsion. The earlier experimentalists had sought to ascertain those forces by the loads required to effect a separation, or to counterbalance their action. Graham proposed the more precise method of computing the magnetic forces from the number of vibrations performed in a given time by the needle; but his suggestion was overlooked, to be afterwards invented again, and generally adopted. The properties of the magnet appear mysterious, though reducible to a few primary facts. But to discover the great pervading principle still baffles the ingenuity and penetration of the most ardent research.

We have briefly adverted to the magnetic theory of Dr. Halley. Alpinus adopted a different and more fanciful hypothesis for explaining the phenomena of magnetism and electricity; he also furnished an improved method suggested by his theory for imparting magnetism to steel bars, by what he called the "double-touch." But, with regard to the mechanical processes for communicating magnetism, they have all been considerably improved by captain Scoresby. Forster made some very important magnetical observations during one of the late polar voyages. But the greatest modern discovery in magnetism is due to Professor Barlow of Woolwich, who has pointed out the mischievous effects produced by the magnetic influence of the metal in a vessel; and suggested a beautiful contrivance for remedying its very injurious influence on the compass.

The science of *electro-magnetism* mainly dates its origin from the time of Oersted, whose first experiments were made early in the present century. Prior to that period, however, we find Franklin, and Van Marum, pointing out the power which a common electrical machine

possessed of imparting magnetism to ferruginous bodies. So powerful was the magnetism produced by the discharge of a small electrical battery, through a wire one-twentieth of an inch in diameter, that it rendered bars of steel two inches long highly magnetic. In Oersted's early experiments, he proposed to ascertain "whether electricity the most latent had any action on the magnet." He soon ascertained that an electrical current passing from the positive to the negative pole of a Voltaic battery would cause a magnetic needle, placed near it, to deviate from its natural position. He was thus led to believe that the electric action was not enclosed within the conducting wire, but that it must possess an extensive sphere of action around it. He was also led to conclude that the above influence acted by revolution; for without such a supposition it was impossible to conceive how the wire, when its position was changed with reference to the needle, should act in opposite directions. Oersted's experiments were no sooner published than they were repeated and varied by philosophers in every part of Europe; and a multitude of new facts were soon brought to light, through the labours of Davy, Faraday, Ampère, Biot, and Arago.*

The study of the heavenly bodies, and as such the dawn of *astronomical science*, must evidently be as old as the creation; though, in all probability, the astronomer of that period confined his observations to the more obvious motions of the sun and moon, the rising and setting of the principal stars, and the apparent motions of the planets. The progress of the sun being thus followed, the regular transitions from day to night would at once be understood. The level and extensive plains of Chaldea peculiarly fitted that favoured portion of the globe to the study of astronomy; and the clear nights which the inhabitants were wont to pass in the open air, united to a pure and serene sky and an unbroken horizon, all conspired to engage that people to contemplate the motions of the stars, and to lead them to conjecture on the laws by which they were governed. From Chaldea, astronomy passed into Egypt, and was soon afterwards carried into Phœnicia, where the people began to apply the observations which had been made to the uses of navigation, and thus rendered themselves both the masters of the sea and of commerce. Their guide, in steering their ships, when far from land, was one of the stars in the constellation called the Little Bear, which, unlike other stars, appeared always to retain the same situation. Other nations, less skilful in astronomy, observed only the Great Bear in their voyages,—a guide too imperfect to enable them to lose sight of land with safety. But the most ancient observations of which we are in possession, that are sufficiently accurate to be employed in astronomical calculations, were made at Babylon, about seven centuries prior to the Christian era: they relate to three eclipses of the moon; and Ptolemy, who has transmitted them to us, employed them for determining the period of the moon's mean motion, and therefore had probably none more ancient on which he could depend. To Anaximander, one of the disciples of Thales, is ascribed the invention of the terrestrial globe, and of a gnomon which he erected at Sparta, by means of which he observed the equinoxes and solstices, and

* A very remarkable fact, for which we are indebted to the latter philosopher, may here be briefly noticed. He found that a needle, suspended over a revolving plate of copper, was drawn aside from the meridian in the direction of the motion, and that, when this became very rapid, it would even follow the tide of circumvolution. It was at first supposed that this very extraordinary effect was produced by the action of a current of atmospheric air; but, when the plate was enclosed in a glass box, the needle still continued to revolve. It may be proper to add that a variety of other bodies were afterwards substituted for the copper plate, with a similar result.

The connection which subsists between the electrical and magnetic influences influenced by heat was, we believe, first pointed out by Dr. Seebeck, of Vienna, in 1823. He found that, by combining metals of different kinds, deflections of the magnetic needle might be produced by a change of temperature alone, without the assistance of any Voltaic arrangement. A very valuable list of thermo-electrics has been furnished by professor Cumming, and M. Ampère ascribes the diurnal variation of the needle to the corresponding motion of the globe, which produces a continued variation in its temperature.

determined the obliquity of the ecliptic, more exactly than had ever been done before. The Greeks, assisted by the instructions they had received from Thales and Anaximander, ventured to make considerable voyages, and planted several colonies in remote countries; yet the latter philosopher and his children were proscribed by the Athenians; and their lives would have been sacrificed but for Pericles, through whose influence the sentence was commuted for banishment. The charge against him was the discovery of truth; for it was thought impious to suppose "that the works of the gods could be subject to immutable laws."

Pythagoras, another disciple of Thales, taught many important astronomical truths. To him is attributed the discovery of the true system of the world, which, after the lapse of many centuries, was revived by Copernicus, and which is now settled on the basis of so many truths that it can never be overthrown. It was thought, even in his school, that the planets were inhabited like the earth; and that the stars, which are disseminated through infinite space, are suns, and the centres of other planetary systems. He is also said to have considered the comets as permanent bodies, moving round the sun; and not as perishing meteors formed in the atmosphere, as they were thought to be in after times. The Arabian school of astronomy commenced with Almamoun, the son of the caliph Haroun al Raschid. This celebrated warrior and philosopher, having conquered the emperor Michael III., made it a condition of peace that a copy of the works of each of the best Greek authors should be delivered to him, and among them were the works of Ptolemy, of which he procured an Arabic translation. This occurred in the ninth century; and, about 400 years later, the work of Ptolemy was translated into the Latin language. The fifteenth century was rendered memorable by the revival of the Pythagorean system. This was effected by Nicholas Copernicus, a native of Thorn in Prussia. The Ptolemaic system, which supposes the earth to be fixed in the centre of the universe, and the sun and moon, with Mercury, Venus, and the other planets, revolving round it in concentric circles, he perceived to be inconsistent with the celestial phenomena, and encumbered with many absurdities, which did not affect the hypothesis which considered the sun to be in the centre, and the earth a planet revolving about it annually, with the rest, and daily turning upon its own axis.

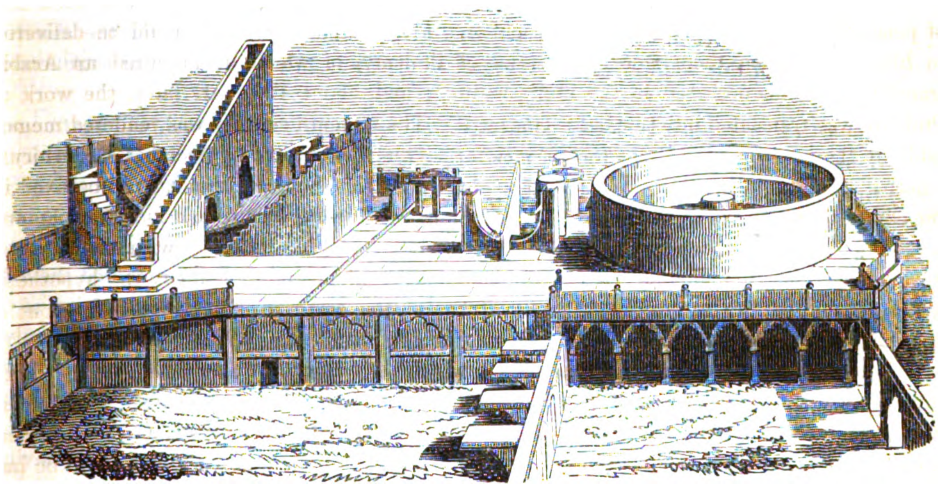
The only opposition of any consequence which the theory of Copernicus ever met with from science and argument proceeded from Tycho Brahe, a celebrated Danish astronomer, who attempted to set up against it a theory of his own. His system is not very different from the Ptolemaic, but is generally called by his name. He supposed the earth to be immovable in the centre of the universe, and the sun to revolve about it every twenty-four hours; the planets, he thought, went round the sun in their periodical times, Mercury being nearest to that luminary, then Venus, Mars, Jupiter, and Saturn; and of course to revolve also about the earth. But some of Brahe's disciples supposed the earth to have a diurnal motion round its axis, and the sun, with all the planets, to move round the earth in one year.

Kepler was one of the pupils of Tycho Brahe, and a man of a truly original genius. Hipparchus, Ptolemy, Tycho Brahe, and even Copernicus himself, were indebted for a great part of their knowledge to the Egyptians, Chaldeans, and Indians. Pursuing paths already pointed out, they did little more than separate fancy from fact, with more or less success; but Kepler, by his own talent and industry, made discoveries of which no traces are to be found in the annals of antiquity. Galileo was contemporary with Kepler; and whilst the latter was tracing the orbits of the planets, and settling the laws of their motions, he was investigating the doctrine of motion in general, which had been neglected for 2000 years; and, from the result of their united labours, Newton and Constantine Huyghens were afterwards enabled to establish the most complete theories of all the planetary motions.

The discoveries of Newton with reference to the laws of gravitation have already been

adverted to; and we may add that from the time of our illustrious countryman, who carried the theoretical part of the science to its present state of perfection, astronomy has never been without an illustrious phalanx of supporters, whose particular discoveries are fully illustrated in the various articles relating to the science of astronomy.

Practical astronomy, to which we must now more particularly direct our attention, appears to have originated in Chaldea; but it found still more active supporters in the Arabian caliphs, and the philosophers who surrounded their courts. The caliph Almanza employed many able mechanics in the construction of instruments for his own astronomical observations; and he was so well provided with apparatus as to be enabled to measure, with tolerable accuracy, an arc of the meridian. Ulug Beg, grandson of the celebrated Tamerlane, was a great proficient in practical astronomy: he is said to have had very large instruments for making his observations, particularly a quadrant as high as the church of Sancta Sophia at Constantinople. But the practical mechanics of the east is, like their political institutions, of a very enduring character; and we still find their astronomical apparatus both accurate and colossal. The celebrated observatory at Benares still exists an enduring monument of the learning and mathematical science of the east; and we furnish our readers with a characteristic sketch of its appearance when visited by Sir Robert Barker.*



The earliest observatory of any importance, established in Europe, was erected by the

* Sir Robert says, when speaking of the edifice, "We entered this building, and went up a staircase to the top of a part of it, near the river Ganges, that led to a large terrace, where, to my surprise and satisfaction, I saw a number of instruments yet remaining in the best preservation, stupendously large, immovable from the spot, and built of stone, some of them being upwards of twenty feet in height; and, though they were said to have been erected many hundred years before, the gradations and divisions of the several arcs appeared as well cut, and as accurately divided, as if they had been the performance of a modern artist. The execution in the construction of these instruments exhibited a mathematical exactness in the fixing, bearing, and fitting of the several parts, in the necessary and sufficient supports to the very large stones that compose them, and in joining and fastening them into each other by means of lead and iron cramps. The situation of the two large quadrants, whose radius is nine feet two inches, by being at right angles with a gnomon at twenty-five degrees elevation, are thrown into such an oblique situation as to render them the most difficult, not only to construct of such a magnitude, but to secure in the position for so long a period, and affords a striking instance of the ability of the architect in their construction; for, by the shadow of the gnomon thrown on the quadrants, they do not appear to have altered in the least from their original position; and so true is the line of the gnomon that, by applying the eye to a small iron ring of an inch diameter at one end, the sight is carried through three others of the same dimensions, at the extremity of the other end, distant thirty-eight feet eight inches, without obstruction; such is the firmness and art with which this instrument has been erected."

landgrave of Hesse-Cassel, in 1561. It occupied the whole upper portion of his palace, and it was well furnished with astronomical instruments. Tycho Brahe, who was engaged about the same period in astronomical observations, very materially improved on the landgrave's apparatus, and made a quadrant capable of showing single minutes. He afterwards erected an observatory in the island of Huenna; it was of a square form, and provided with two lofty round towers. The instruments consisted of quadrants, sextants, circles, astrolabes, globes, clocks, and sun-dials. These instruments were so divided as to show single minutes; and in some the arc was so divided as to be read off into ten seconds. Most of the divisions were diagonal; but he had one quadrant so divided as to form forty-seven concentric circles. The whole expense attendant on the erection of his observatory is said to have amounted to 200,000 crowns.

In 1671 the royal observatory at Paris was finished, and the use of it assigned to M. Cassini, after it had been furnished with instruments at a very great expense. The erection of the Greenwich observatory, five years afterwards, may be said to form an era in practical astronomy. Mr. Flamstead was appointed the first astronomer royal, and the office has since been held by several distinguished mathematicians. In the beginning of the last century the practice of astronomy made but little progress, in consequence of the imperfect apparatus employed; but since that period the names of Hooke, Graham, Bird, Dolland, Ramsden, Troughton, and Herschel, as practical artisans, give abundant warrantry for the assertion that the natives of this country exceed those of all others in the construction of astronomical instruments.

The art of *navigation* is closely connected with astronomy, and as such will next engage our attention. Its origin, like that of most other arts, is involved in the fabulous history of early times; but, according to the accounts of the most ancient historians, it was in the Mediterranean and Arabian gulfs that the first attempts were made in the art, as in those places commerce assumed an active character in the intercourse between the Egyptians and Phœnicians. The former, who lived in a fertile land and a genial climate, which rendered them independent of the productions of other countries, devoted themselves to the cultivation of the sciences rather than that of commerce, and, imbued with gross superstition, applied only a portion of their knowledge of astronomy to navigation. But the Phœnicians, whose country was unequalled in its beauty, less superstitious, and of a more active and commercial disposition, boldly extended their voyages, and established their colonies nearly in every country that was known. They improved the construction of their vessels; they forwarded navigation as much as the period admitted; and they became the teachers of this art to all nations, particularly to the Gaditanos (inhabitants of Cadiz) and the Greeks. The Carthaginians and Romans succeeded them; but, although each in their turn improved their ships, the knowledge, geography, and navigation, limited to the mere performance of short voyages, would have remained in its infancy, had not the progress of mathematics, and particularly that of astronomy, in modern ages, roused it from its lethargic condition. Navigation at that period consisted only in the knowledge of coasts, and in making short voyages from one place to another, without losing sight of the land; and when, by any unforeseen accident this became invisible, the motions of circum-polar stars, and the flight of birds, naturally directed towards the shore, served as guides to the bewildered mariner. The configuration of coasts, and their mountains and principal headlands, with the use of the lead, formed another species of knowledge, for which the mariner was indebted to his experience in navigation.*

* Until the properties of the magnet were discovered, followed by the invention of the compass, the progress of navigation could not be otherwise than slow; and therefore, from this important period, which was about the end of the thirteenth century, the real advancement of this art towards perfection can only be dated. The valuable invention of the compass is equally involved in mystery, and its real discoverer is unknown.

"But little avail would it be to the mariner," says Salazar, "to know the course which his vessel may make with respect to the shore; or the means of measuring the distance she might sail, unless he possessed some method of comparing his situation with reference to the various parts of the earth's surface, when alone and forsaken in the vast watery desert, where the eye can discover only sea and sky. In this condition, astronomy is ready to assist him, and to afford him the means by which his latitude and longitude may be ascertained, and with these data he finds out the position he occupies on the globe. But even this is insufficient to enable him to shape his course in his lonely situation, surrounded on all sides by the element alone in which his vessel moves, nor can he yet direct her to the port he is seeking, or avoid the dangers he may meet in his way. The mariner, unless he knows the relative situation of the place to which he would go, must still be at a loss what to do; and, to ascertain this, he must be informed of the contour and direction of coasts, their respective positions, the motions of the tides and currents, the gulfs and depths of the sea, as well as the innumerable rocks with which it is scattered. Such are the important objects which constitute hydrography, all of which are essential to his safety and convenience.

The exact epoch is not known, with any probable degree of certainty, when seamen first made use of maritime charts, the ingenious invention and valuable guides with which geography has furnished navigation, and which, being gradually improved, have now arrived at that state of perfection which enables the navigator to traverse the ocean with the same confidence that a traveller would perform his journey across a country.

The celebrated prince Henry of Portugal, seeing the importance of advancing this branch of navigation, in the year 1417, founded an academy for pilots and mathematicians at Sagres, and established as the president of it *Maestro Jayme*, an experienced pilot of Majorca, one who was well acquainted with such matters. This person instructed young Portuguese officers in the use of the astrolabe, and the method of finding the latitude by means of the sun's altitude, having previously constructed tables of declination.

Hutton, in his *Mathematical Dictionary*, says that Ptolemy was the first to whom the idea occurred of varying the proportion of the degrees of latitude, and that Gerard Mercator, in 1556, published charts on the principle of those which now bear his name; but that Edward Wright was the first who conceived the true principles of constructing these charts in 1599, and that Mr. Blundeville published an account of Wright's charts in 1594. Such was the state of navigation at the end of the fifteenth century, when Columbus, well versed in the astronomical and mathematical knowledge of his day, and endowed with an extraordinary degree of intrepidity, boldly ventured across the ocean, traversed unknown seas, and, by discovering new countries, produced a total change in politics and science. In his first celebrated voyage, he discovered the variation of the needle, a phenomenon which, to his companions, appeared so wonderful, that, fearful of its losing altogether the virtue of pointing to the north, they imagined they must become victims to the ambition of this great man. But the safety of the navigator was yet imperfect, and a method was still wanted by which he might find his longitude at sea, and which, although it might not arrive at that degree of precision by which the course of a vessel could be found, should at least afford an approximation

Lafiteau, in his *History of the Portuguese Discoveries in the New World*, says that Vasco di Gama brought it to Lisbon from the coast of Africa, on his return from Melinda, where the Arabs then used it, and he believed the Portuguese to have been then ignorant of it. Some attribute it to Flavio Gioja, of Amalphi, about the year 1302; while others again are of opinion that the invention is due to the Chinese, and that one of their emperors, a celebrated astronomer, was acquainted with it 1120 years before the Christian era; nor have others again been wanting who have supported the opinion that it was known in the time of Solomon. The ancient Greeks and Romans are supposed by some to have used it, but the silence of Pliny on this subject renders this doubtful.

to it. For this purpose, various methods were proposed, all grossly defective, until astronomy again came to the aid of navigation. Hipparchus, the inventor of the use of longitude in charts, was acquainted with no other method of finding it than by eclipses of the moon. Kepler added those of the sun, at the expense of a vast deal of calculation; but, as each required that the observer should remain stationary, their methods were of no service to the navigator. The first person to whom it occurred to find the longitude by means of lunar distances was Pedro Apiano, in the year 1510; but his method was neglected, because it was deficient of the necessary corrections for parallax and refraction, in consequence of which it gave results that were even more erroneous than those obtained only by estimation. His contemporary, Reynero Gemma, adopted the same method, but fell into similar errors. To remove these difficulties, Philip III., in 1598, was the first to offer a considerable reward to the person who should discover a method of finding the longitude at sea that would not only serve to determine the situation of the ship, but would also improve the state of the charts. The Dutch government next followed this example, and in 1714 the British government voted 2000*l.* to perform experiments, and a reward of 10,000*l.* to the person who should find a method of ascertaining it within one degree of the truth; also 15,000*l.* if it came within two-thirds of it, and 20,000*l.* should it come within half a degree; but if the method employed was that of the distance between the moon and sun, or stars, 5000*l.* were offered to bring it within fifteen minutes of error in the distance, which is equal to seven minutes of longitude. With these encouragements, men of science applied themselves to gain the promised reward in Spain, France, and in England, as well as in other parts of the world. They invented various instruments and methods; but the results obtained did not fall within the proposed limits. The application of Jupiter's satellites by Galileo, previous to this, for determining the longitude, was more effectual; but these observations, so valuable for places on land, were unavailable at sea. The Spanish pilot, Andres de San Martin, in the voyage which he made with Magellan, had already employed the method with which Ruy Fallero had supplied him, of determining the longitude by lunar distances; but the results he obtained not being, as he considered, correct, with much discernment he attributed it to errors in the tables of the sun given in the almanac, satisfying himself that while they remained so the problem would never be determined. At the end of this century, Pedro Sarmiento de Gamboa, one of the most expert navigators of his day, obtained the longitude at sea by the lunar distances, which he measured with an instrument of his own making, and his results were so good that he was enabled to correct the reckoning of his ship, which he ascertained amounted to 220 leagues of error. But his invention was lost, as he did not make it known.

Gemma Frisius is the first who mentions the use of time-keepers; and, in 1665, a very interesting attempt was made to apply them in a voyage to the coast of Guinea, by major Holms, with a watch made by Huyghens. With this the longitude of the island of Fogo was obtained with tolerable precision. Tully followed up the art, and, in 1714, published a work on finding the longitude at sea by means of chronometers, and continued his studies at Paris. Julian le Roy was his pupil; and the son of this latter and M. Berthoud carried on the subject with more success than had hitherto been known. In 1726 Mr. Harrison produced a chronometer the error of which did not amount to one second in the space of ten years. Further improvements were subsequently made by the same ingenious artist, as well as by Earnshaw, Vulliamy, &c.; and the time-piece is now employed with great advantage for nautical purposes.

The true principles of the art of navigation appear to have been settled by Wright, Bond, and Norwood; and the subsequent discoveries of Cook and the other voyagers, who were so warmly patronized by George III., formed a distinct era in this branch of science. The voyages of discovery lately undertaken to the polar regions have also furnished con-

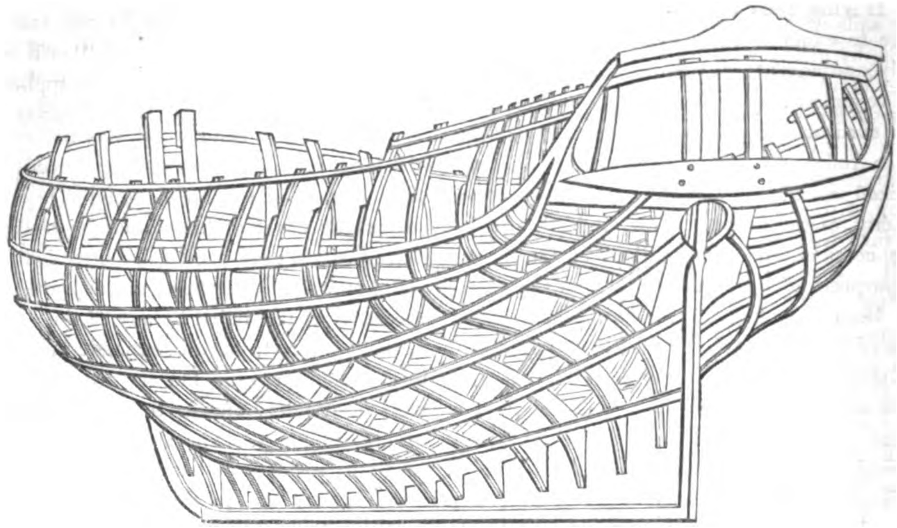
siderable advantages both to the practical and theoretical navigator; so that the sailor is now enabled to calculate with amazing precision, not only the probable effects of winds and currents on his course, but to predict with accuracy the day, and almost the hour, when his voyage will be terminated.

Having thus traced the progress of navigation from its earliest dawn, we may briefly pause to examine the vessels that have been employed at different periods for carrying the hardy and adventurous mariner over the trackless ocean. There is little doubt but that the first voyagers employed the trunk of a tree, which was afterwards expanded into a raft, for their earliest essays in navigation. Soon, however, the mass of solid wood was hollowed into a rude and mis-shapen canoe; and at a still later period the wants introduced by civilized society rendered it necessary to increase the freight, and consequently the capacity, of the vessel. Now, indeed, the business of the naval architect may be said to have commenced. The galleys of Greece and Rome, which were principally intended for the purposes of war, were formed on the most graceful and elegant models, and appeared to have been propelled with a degree of velocity scarcely to be paralleled by any of the war-boats of the present day. But little progress, however, appears to have been made in naval architecture by the commercial nations who rose in the middle ages. The huge carracks of Spain and Portugal, like the well-freighted argoseis of Venice, appear to have been intended rather for convenience of freight than external adornment. The ships of war were evidently moulded on the same plan; but vastness still appears to have been the great desideratum. The "Great Harry" was a perfect monster of the deep; its forecastle towered over the element on which it floated; and it was fitter for a floating battery than a sailing vessel. The English war-ships of that period were generally employed for commercial purposes and long voyages; while the greater part of the Spanish vessels, destined to compose the Armada, were mainly such as we have now been describing. Hence the greater facility which the English found in manœuvering their vessels, to which the destruction of the Spanish flotilla may be principally ascribed.—Passing over a period of nearly three centuries, we find but little progress made in naval architecture; and it is to the French and Germans, proverbially the worst sailors in Europe, that we must ascribe the first attempt at applying mathematical science to ship-building. Louis XVI. patronized naval science; and Napoleon established a college for the education of a race of scientific shipwrights. In our own country but little was done prior to the improvements introduced by Seppings, whose labours are fully detailed in the article NAVAL ARCHITECTURE.

One of the most curious features in connection with naval architecture is the speed with which a large vessel is now constructed. A few months will suffice to convert the tall and majestic oak of the forest into a portion of the frame-work and timbers of a large vessel. The iron and the copper, which lie buried deep in the bowels of the earth, are as rapidly raised to its surface, and converted into the sheathing and bolts, which connect together the huge structure. The hemp and the flax, which are seen as waving ornaments in our fields, become connecting chains to attach the bark to the bed of the ocean; and the tar sealed up in the heart of the lofty pine serves to lubricate its elastic coils. The vessel thus rapidly, yet perfectly formed, obeys each command of the mariner; goes before the wind, and almost against it; and forms for him a secure and stable mansion, in the midst of the most stormy ocean.

The frame-work of a ship furnishes a beautiful example of strength, durability, and lightness, and, when we bear in mind the massive and precious freights that are brought from the most distant regions of the earth in their capacious receptacles, it will be obvious that no ordinary care should be bestowed on their construction. The theoretical shipwright, pursuing the best of all possible paths, has evidently gone to nature for his guide in giving

strength to the superstructure. He has combined the osseous frame-work of the bird with the lightness and power of motion exhibited by the fish; but this miracle of human art must be stripped of her outer cerements to be properly appreciated, and in this form we present her to the reader in the subjoined engraving.

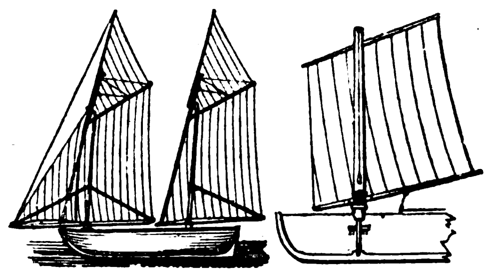


It is clear that the stability of the vessel will in a great measure depend upon the weight and position of her keel, which is usually so formed as to give the preponderance to that side of the vessel. In some modern improvements the keel is made movable, so that it will ascend and descend precisely in the same way as the feet of a bird are elevated and depressed, when flying through the air, and this forms a beautiful example of the adaptation of a natural action to an artificial structure. The rounded and expanded bow is as well fitted for the conveyance of freight as it is for speed; whilst the helm, acting like the tail of the fish, serves to guide the body in any required direction. The inhabitants of the air, like those of the waters, are usually provided with a smooth external covering, to facilitate their passage through the fluids they respectively inhabit. The sheathing of a ship answers a similar purpose; and Sir Humphry Davy has beautifully applied the principles of chemical science to its protection when exposed to the action of sea-water.

Passing from the hull of the vessel to the means by which she is propelled, we find but few early attempts to construct standing rigging. In some of the sculptured representations of Egyptian vessels, we find a mast and flag, though a sail is but rarely delineated. Even in the best days of Greece and Rome, the oar was generally employed both for commercial and military purposes; and, when canvas was resorted to, it appears to have been attempted with fear and trembling. The paddle is still the ordinary instrument of propulsion with most savage nations, though a bamboo mast, and bark sail, are sometimes added.

The motion of a ship in the water is well known to depend on the action of the wind upon its sails, regulated by the direction of the helm. As the water is a resisting medium, and the bulk of the ship considerable, it thence follows that there is always a great resistance on the fore-part of the vessel; and, when this balances the moving force of the wind upon the sails, the ship may be said to have attained her utmost degree of velocity, and her motion is no longer accelerated. If the sails occupy too extended a space, and be raised too high above the centre of gravity of the vessel, the first gust of wind is liable to destroy the equilibrium, and upset the vessel. To prevent the danger which would result from this circumstance, the sails of a vessel are rendered movable. More or less canvas may thus be employed as oc-

casion requires; and, in the event of a hurricane, the whole of the canvas may be removed from the rigging. A very ingenious contrivance has been suggested in the present century for preserving the equilibrium of a vessel and her rigging. It consists in balancing the mast, which revolves on axes beneath the deck, so that when a sudden gust of wind acts upon the sails with a tendency to overset the vessel the hull remains nearly stationary, and the sails, by giving way, form a species of inclined plane for the wind to pass over. It will however be obvious that this plan is only fitted for small craft. Another contrivance applicable to somewhat larger vessels, and of a still later date, is represented in the subjoined wood-cut.



Lieutenant Shuldam proposes by this arrangement to materially diminish the labour of working the sails, by causing them to turn with the masts upon pivots in the hull. This may be effected either by the action of the wind upon the sails or by manual labour. One of the figures exhibits the principle applied to a boat, and the other to a larger vessel; but in the latter case it will be necessary to form the masts of four spars raised upon a cross piece at bottom, and united at top to a cap or mast-head, thus forming an open pyramidal mast.

The history of navigation would be obviously imperfect without some reference to the progress of the steam-boat as applied to nautical purposes. We can hardly conceive a more extraordinary monument of human ingenuity than a steam-boat—a mere hull, as it were, furnished with one of these potent prime movers, and breasting her way against both wind and tide. Our transatlantic brethren, who erroneously claim the credit of having invented the steam-boat, certainly have the merit of first employing it usefully on their vast inland waters.*

We might have observed in passing that the steam-boat was really invented by an ingenious mechanic named Jonathan Hulls, early in the eighteenth century. He proposed to employ the atmospheric steam-engine, acting on a large revolving paddle-wheel placed in the stern of the boat. But how different is the first dawn of this invention from its consummation in the present day! Darwin exclaimed, in the spirit of prophecy, long before steam-boats were employed,—

> Soon shall thine arm, unconquered steam, afar
> Drag the slow carriage, and impel the rapid car,
> Or on wide-waving wings expanded bear
> The flying chariot through the fields of air.

Little however could the ingenious philosopher, who thus poetically describes the advantages of the steam-engine, have contemplated all the importance of this discovery. In a commercial point of view it is second only to that of the ship itself, and, by rendering ineffective the attempts at naval aggression on the part of other nations, it bids fair to secure to us all the advantages of a secure and lasting peace.

* The earliest appearance of a steam-boat on the great river Hudson appears to have excited the most lively emotions of fear and dismay, and has been thus described by the biographer of Fulton :—"The first steam-boats used dry pine-wood for fuel, which invariably sent forth a column of ignited vapour and sparks, many feet above the flue. This uncommon light first attracted the attention of the crews of other vessels. Notwithstanding the wind and tide were adverse to its approach, they saw with astonishment that the vessel was rapidly coming towards them; and, when it came so near that the noise of the machinery and paddles was heard, the crew shrunk beneath their decks from the terrific sight, and left their vessels to go on shore; while others prostrated themselves, and besought Providence to protect them from the approaches of the horrible monster which was marching on the tides, and lighting its path by the fires which it vomited."

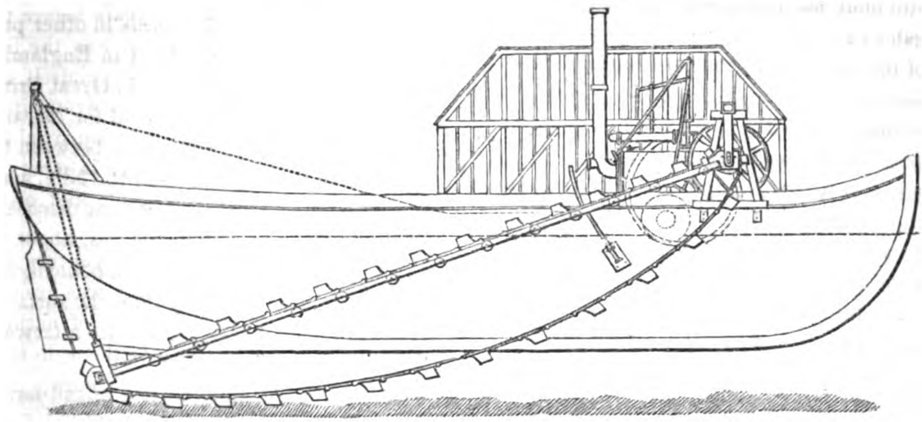
The *inland navigation* of this country has made an amazing progress since the commencement of the present century; and its effects are equalled only by those produced by the still more modern improvements of rail-roads. It was, however, in the middle ages that navigable canals began to be considerably multiplied; first in China, and afterwards in other parts of the world. The canal from the Trent to the Witham, which is the oldest in England, is said to have been dug in 1134. Now, however, almost every principal town in Great Britain is furnished with one or more of these fluid roads. Egypt has been celebrated for its canals from the earliest periods of history. The principal are the canal of Alexandria, between that city and Rosetta and the Nile, and parallel to it; and that of the Red Sea and the Nile, across the isthmus of Suez. The existence of this last, though a subject heretofore of some discussion, is now established beyond doubt. It was begun by Necho, son of Psammeticus, about 616 B. C., and the work was continued by Darius Hystaspes, but was afterwards abandoned, from fear of inundating a great part of Egypt, which was supposed to be lower than the surface of the Red Sea. The work was, however, resumed, and completed nearly a century afterwards, about 521 years before the Christian era, by Ptolemy II.

If we may believe the Chinese Annals, they must have had an extensive inland navigation at a period much earlier than any other country of the world. The only Chinese canal our space will permit as to notice forms part of the line of transportation between Pekin and Canton. Its route, including sinuosities, is said to exceed 500 miles. Italy holds a foremost rank in the march of improvement; and it was in that country that locks and sluices to pass boats from one level to another were first introduced. It was the invention of two engineers of Viterbo, brothers, whose names have not been recorded. This improvement was soon after adopted in the Milanese territory, under the direction of Leonardo da Vinci, the celebrated painter, who was also a skilful engineer. Inland navigation became so important that the Italian governments paid great attention to it, and enacted many regulations on the subject, and numerous treatises were published on the construction of locks, and the art of making and managing canals. The following are some of the principal canals of modern Italy:—The Naviglio Grande, between Milan and the river Tesina, fifteen miles in length, 130 French feet broad at the surface, and forty-six at the bottom. It was extended to Milan in 1257, and enlarged in 1269, with a branch of about eleven miles in length fpom Albiato southward. The Martesena canal branches off from the right bank of the Adda, near Contessa; is twenty-four miles in length and thirty-three feet in breath, and is raised in some places, by walls and embankments, 110 feet above the level of the river. In 1497, five locks were introduced into this canal.

Canal navigation has made considerable progress in France: indeed we believe at the present time they possess rather more than 1000 miles of artificial canals fitted for the navigation of boats. The first important work of the kind was the canal of Briare, completed in 1642; but the most extensive line of inland navigation in France is the canal of Languedoc, which forms a communication between the Mediterranean and the Atlantic Ocean. The first considerable work of this kind in our own country was executed by the duke of Bridgewater. This patriotic nobleman devoted the whole of his time and a large fortune to the project, and was rewarded by the most complete success. Our space will not, however, permit of any detailed account of the progress of canal navigation, which appears to offer commercial advantages second only to those of locomotion. It may be enough to add that there are in our own country more than 200 of these arterial ramifications, which benefit agriculture and spread happiness and fertility through their paths.

Canals and navigable rivers which tend seawards have usually a disposition to form bars, which speedily choke the mouth of the stream, and impair, if not destroy, the navigation. The ancients had no means of removing these barriers to commerce, and some of the oldest

harbours were of necessity abandoned from the circumstance. But the steam-engine, which may not unaptly be termed the "master-worker" of modern times, furnishes us with an effectual remedy for this inconvenience.



The ancient chaplet or bucket-pump is here seen put in operation by this gigantic prime-mover, and it digs and clears away the obstructing matter at a considerable depth beneath the surface of the water as freely as it would on land.* Now those who have witnessed the laborious operation of "ballast-heaving," as it is called, must at once feel the amazing advantages of this process. When conducted on a large scale, it costs considerably less than the old method, without outraging the feelings of humanity by a view of the almost super-human tasks inflicted on our fellow creatures by the former system.

Passing from the contemplation of the wonders of mechanical skill, as displayed in the artificial operation of fluid bodies, we come to examine the history of *anatomy*, and trace the progress of human knowledge in the most important of all the sciences. Man, in the earliest stages of society, must soon have acquired some notion of the structure of the animal frame, particularly of the external parts, and some even of the internal, such as the bones, joints, tendons, and blood-vessels, which are exposed to the examination of the senses in the living body. This rude species of knowledge was indeed gradually improved by the accidents to which frail mortality is exposed, both by the necessities of life, and the various customs and superstitions of different nations. Thus, the observance of bodies killed by violence, attention to wounded men in many diseases, the various ways of putting criminals to death, the funeral ceremonies, and a variety of occurrences, must have shown men more and more of themselves, and their own wonderful organization. This knowledge was, however, of a very general or popular character. Anatomy, properly so called, or the knowledge obtained by dissections, expressly instituted for that purpose, is of a more recent origin. It seems now to be clearly ascertained that writing, and many other useful and ornamental inventions and arts, were cultivated in the eastern parts of Asia long before the earliest times that they are treated of by the Greek or other European writers, and that the arts and learning of the east were, in subsequent ages, gradually communicated to adjacent nations, especially by the medium of traffic. The customs, superstitions, and climates of eastern countries appear, however, to have been as unfavourable to practical anatomy as they were inviting to the study of astronomy, geometry, poetry, and all the softer arts of peace. In warm climates,

* The harbour of Alexandria had become so choked by sand that it had almost become valueless for vessels of heavy burden. The present pacha applied to Mr. Galloway, the eminent engineer, for assistance in the matter, and he constructed two large machines, and, motion being given to them by oxen, the harbour was speedily restored to its original state.

animal bodies run so quickly into putrefaction that the early inhabitants must have avoided such offensive employments as were essential to anatomical enquiries; in fact, it does not appear, by the writings of the Grecians, Jews, or Phœnicians, that anatomy was particularly cultivated by any of those nations. Hippocrates, who lived about 400 years before the birth of Christ, was reckoned the eighteenth in descent from Æsculapius, and was the first physician who separated the professions of philosophy and physic and devoted himself exclusively to the latter pursuit, and is generally supposed to be the first who wrote upon anatomy. If, however, we read the works of this distinguished philosopher with impartiality, and apply his statement of the parts to what we now know of the human body, it must be allowed his descriptions are very imperfect, incorrect, sometimes extravagant, and often unintelligible.

From Hippocrates to Galen, who flourished towards the end of the second century, the decline of the Roman empire, that is, in the space of 600 years, anatomy was greatly improved, philosophers considering it as a most curious and interesting branch of natural knowledge, and the physicians as a principal foundation of their art. Both of them, in that interval of time, contributed daily to the common stock of knowledge, by more accurate and extended observations. Aristotle, a disciple of Plato, and preceptor to Alexander the Great, formed the most enlarged design which perhaps was ever conceived by man; no less than a general and detailed history of all nature, a plan by far too vast for the short life of any individual. The love of science, which distinguished Alexander the Great scarcely less than his ambition and thirst for glory, led him to encourage and assist the plans of Aristotle in a manner worthy of so great a prince. The sum of money devoted to his works on natural history would be almost incredible did we not consider the great resources and profuse liberality of Alexander, and was not this circumstance stated by writers of unexceptionable authority. Athenæus, Pliny, and Ælian, concur in representing it at between 100,000*l*. and 200,000*l*. Shortly after the foundation of Alexandria, a celebrated school was established there, to which the Greeks and other foreigners resorted for instruction, where physic and every branch of natural knowledge were taught. Herophilus and Erasistratus, two anatomists of this school, particularly celebrated in the history of anatomy, seem to have been the first who dissected the human body: for in the time of Aristotle animals only were dissected.

The Romans, in prosecuting their schemes of universal conquest and dominion, soon became acquainted with the Greeks, and the intercourse of the two nations was constantly increasing. Thus the arts, the philosophy, and the customs of the Greeks were introduced into Italy. Military glory and patriotism, which had formerly been the ruling passions of the Roman people, now began to give place to the more refined arts of peace; thus literature and philosophy were transported from the Greeks to the Romans, and gave rise to the taste and elegance of the Augustan age. In this way did conquered Greece triumph over the unpolished roughness of her conquerors. Galen, who was physician to four emperors, resided chiefly at Rome; he arranged all the prior anatomical science that Herophilus and Erasistratus had obtained from the actual dissection of human subjects, and incorporated it into his voluminous treatises on the different branches of medicine. The medical principles of this great man, formed on the peripatetic philosophy of Aristotle, are not to the present purpose, except that they reigned triumphantly in the schools and universities, disdaining and crushing all the innovators or improvers, for a period of nearly 1500 years. Galen was the first author who seems to have digested in regular order the human functions, the brain and its membranes, the senses, the contents of the thorax and abdomen, osteology, a complete myology, and neurology, in which are the origin and insertions of the muscles, their actions, &c., and the distribution of the whole nervous system. The lacteal vessels

were likewise well known, though the extent of their effects, their passing through the thoracic duct and subclavian vein to the blood, were not comprehended. Anatomy, however, experienced the same fate as learning in general, on the decline and fall of the Roman empire. The moral and intellectual character of the Romans had been much debased in the latter ages of the empire, and the successive irruptions of the northern barbarians accelerated the approaching fall. The inundation of the Goths into Italy, in the fifth century, extinguished with the Roman empire its laws, manners, and learning, and plunged the world into the depths of ignorance and superstition. The succeeding ten centuries, which have received the appellation of the dark ages of the world, presents a melancholy picture to the philosophical observer of human nature, a barren and dreary waste, unenlivened by a single trace of cultivation.

Among the circumstances which contributed to the restoration of anatomy is to be reckoned the assistance which it derived from the great painters and sculptors of the age. A knowledge of the anatomy of the surface of the body, at least, is essential to the prosecution of these arts. Michael Angelo dissected men and animals, in order to know the muscles which lie under the skin. A collection of anatomical drawings made by Leonardo da Vinci at this period is still extant, and, with subjoined explanations, formed part of the library of his late majesty. Dr. Hunter has borne witness to the minute and accurate knowledge which these sketches discover, and does not hesitate to consider Leonardo da Vinci as the best anatomist of his time. About the middle of the sixteenth century appeared Vesalius, who may with propriety be termed the restorer of anatomy, being the first who dared to expose the errors of Galen, in medicine and anatomy, by referring to the human body.*

Vesalius published in 1539, at the age of twenty-five, his grand work on *the structure of the human body*, with numerous elegant figures, supposed to have been drawn by the celebrated Titian. This work contains such a mass of new information, that it may justly be considered as forming an era in the history of anatomy.

Falopius comes next in order. He was a friend and pupil of Vesalius, and published a most extraordinary work on the same subject. The beginning of the seventeenth century is remarkable for the discovery of the most important function of animated bodies, viz. the circulation of the blood, by our celebrated countryman, Dr. William Harvey. In the year 1616, Dr. Harvey read a course of lectures, in which he first illustrated his views relating to the circulation of the blood, which some judicious anatomists had only conjectured to exist in a vague and confused manner, and had only known it to take place in some particular part. From this period, Harvey demonstrated and taught in his public lectures, and by simple and clear experiments proved to the most sceptical, that the blood not only traversed the structure of the lungs, but that it also circulated through every part of the body, by means of an admirable arrangement, on which depends the life of man. He fully illustrated the alternate contraction and dilatation of the heart, the passage of the blood through the lungs, its reception into the left auricle from the pulmonary veins, its expulsion from thence into the left ventricle, by which it is propelled through all the arteries of the body, and returned by the veins. So clearly were the phenomena of the whole circulation understood, and so admirably explained by Dr. Harvey, that, although he wrote two centuries ago, this function has never been laid down with more truth, simplicity, and elegance.

After the discovery and knowledge of the circulation of the blood, the next question

* He was born at Brussels, in 1514, and studied successively at the different universities of France and Italy. Thus he acquired all the knowledge of antiquity. Not content with this, he took every opportunity of examining the human body, and followed the army of the emperor Charles V. into France for that purpose in 1535. Vesalius was the first who maintained that dissection was the proper way of learning anatomy, in opposition to the study of the works of Galen.

would naturally be about the passage and route of the nutritious part of the food, or chyle, from the bowels to the blood-vessels. The name of Asellius, an Italian physician, is rendered illustrious by the discovery of the vessels which carry the chyle from the intestines. He observed them full of a white liquor in the mesentary of living animals, and from this circumstance called them milky or lacteal vessels. For many years the anatomists in all parts of Europe were daily opening living animals, either to see the lacteals or to observe the phenomena of the circulation. In making an experiment of this kind, Pecquet, in France, in the year 1651, was fortunate enough to discover the thoracic duct, or common trunk of all the lacteals, which conveys the chyle into the subclavian vein. And now the lacteals having been traced from the intestines to the thoracic duct, and that duct having been traced to its termination in a blood-vessel, the passage of the chyle was completely illustrated. The discovery of the absorbent vessels in various parts of the body, where they are known by the name of lymphatics, from the transparent colour of their contents, very soon followed that of the lacteals and thoracic duct. They were discovered in the year 1653. Rodbek, a Swede, is generally allowed to be the first who discovered these vessels; but this honour was disputed with him by Bartholin, a Dane, who has however obtained additional credit from his having entertained very accurate ideas of the physiology of the lymphatic system, which was afterwards more fully elucidated by Glisson. By these vessels the old particles of our bodies, which are no longer fit to remain in it, are removed and conveyed into the blood, to be rejected or thrown out by the excretory organs.

Leuenhoek took up the subject of anatomical enquiry where others had left it. He investigated the minute structure of the body by means of magnifying glasses, and was thereby enabled to demonstrate the circulation of the blood in the pellucid parts of living animals, and the red globules of the blood. Malpighi also directed his attention chiefly to the development of the more minute portions of the human structure, especially of the glands or secretory organs of the body. About this time anatomy made two great steps by the invention of injections, and the method of making anatomical preparations. For these we are indebted to the Dutch, particularly Swammerdam and Ruysch. The anatomists of former ages had no other knowledge of the blood-vessels than what they could collect from laborious dissections, and from examining the smaller branches of them on some fortunate occasion, when they were found more than commonly loaded with red blood. But filling the vascular system with a bright-coloured wax enables the anatomist to trace the large vessels with great ease, renders the smaller much more conspicuous, and makes thousands of the very minute ones visible, which, from their delicacy and the transparency of their natural contents, are otherwise imperceptible. The modern improved methods of preserving animal bodies, or parts of them, in spirits and saline solutions, has also been of the greatest service to anatomy, especially in saving the time and labour of the anatomist in the nicer dissections of the small parts of the body.*

It would occupy too much space to detail the labours and discoveries of all the eminent men who have distinguished themselves in anatomy during the last century. We may, however, state generally that every part of the human body has been most minutely and elabo-

* The act of parliament, which passed in 1832, for regulating the supply of subjects for dissection, and for legalizing the same, has been of the greatest importance; for, although the supply is still insufficient for the great number of pupils who annually resort to London for prosecuting their medical education, yet it has the following great advantages:—It prevents the recurrence of those dreadful murders which were perpetrated by Burke and Hare in Edinburgh, and by Bishop and Williams in the metropolis; and, secondly, it has removed the necessity of the anatomical professors and students being compelled to purchase subjects from the lowest and vilest of mankind. There are, however, many objections to some parts of the statute, which no doubt the executive will remove, when the necessity for doing so is pointed out.

rately examined and described, and accurate and elegant engravings have appeared of every part: so that a student of the present day possesses the greatest facilities for the prosecution of his anatomical labours. The bones and muscles have been most elaborately represented and described by Albinus, Cheselden, Cowper, John and Charles Bell, and Lizars. The vascular system has been illustrated by a splendid work of the baron Haller. Meckel of Berlin, and Scarpa at Pavia, and Sir Charles Bell in England, have bestowed equal or even superior diligence in tracing the distribution of the most important nerves, and faithfully delineating them. Dr. Cruikshank distinguished himself by an excellent work on the absorbent system; and Mascagni has given to the public a most elaborate account of the absorbent system, with splendid plates. Dr. Hunter, to whom anatomy owes more in this country than to any other individual, published a complete history, with beautiful explanatory engravings, of the growth of the human ovum. His brother, the late Mr. John Hunter, also deserves to be mentioned in this place, as an accurate and minute dissector, and a laborious experimentalist. He surveyed in his researches the whole field of animated nature, and greatly promoted the science of physiology. He formed also one of the grandest and most beautiful anatomical museums in Europe, which precious treasure passed into the possession of the Royal College of Surgeons. The next collection to John Hunter's was that of the late Joshua Brookes, which, to the disgrace of an enlightened country, was dispersed by the hammer of an auctioneer, although only 10,000*l.* was the sum required for a museum that had cost him forty years of devoted attention.

The structure of the brain has been represented with unrivalled elegance by Vicqd 'Azyr, a French anatomist. Some parts of this important organ have also been illustrated by the labours of Söemmering, who prosecuted the study of anatomy with unwearied industry. The splendid works of Jules Cloquet, now publishing by professor Quain, of the University of London, bids fair to be an invaluable addition to the student's library. The fine works of Sabatier, Winslow, Heister, Bichat, Weber, Automarchi, Tiedemann, Munro, Tuson, &c., are highly deserving the public attention, and it is to be lamented that their high price should preclude pupils generally from enjoying the advantages that must accrue from consulting them. The new doctrine promulgated by Drs. Gall and Spurzheim, under the title of *Phrenology*, has gained a considerable share of attention, and has been ably illustrated. We have from the hands of Söemmering two most finished productions in every respect on the anatomy of the eye and ear: but it would be unjust not to enumerate with a due tribute of applause the labours of Zinn, Scarpa, Lizars, and Dewhurst, on the same subjects. Morgagni, who taught anatomy in Padua, published a work of great utility on pathological anatomy. He has been followed in this country by the late Drs. Baillie and Armstrong; and it is but justice to state that the graphic illustrations attached to works of this character are very scientific and accurate.

Having said thus much respecting the history of anatomy, we shall now take a similar retrospect of the science of *medicine*. With regard to the early history of medicine, Schultze, professor at Altorf in the beginning of the eighteenth century, has traced it to the fall of man, showing with great gravity that Adam and Eve were likely to discover some remedial agents for the cure of those maladies which an indulgence of their appetites was likely to create. The most ancient physicians we read of were those who embalmed the patriarch Jacob, by command of his son Joseph. It is not improbable that among the Egyptians religion and medicine were originally combined; and most writers are of opinion that the priests were the physicians of both the Egyptians and the Israelites for a considerable period: but after the liberation of the latter they were disunited, and after that time the word *physician* is very commonly employed, and totally distinct from that of priest; for we read that when one of the kings of Israel was diseased in his feet, "he sought not the Lord, but

went to the physicians." Hence we may conclude that among the Jews medicine was looked on as a mere human invention. The Egyptians believed that the science of medicine was invested in Thoth, the Hermes or Mercury of the Greeks. His name is said to have been written on pillars in hieroglyphics, in order to perpetuate his knowledge. The Greeks also had several deities to whom they attributed the invention of physic, particularly Prometheus, Apollo, and Æsculapius, the latter being the most celebrated. If we may believe the ancient poets, the warriors were physicians also; for according to them the knowledge of medicine was universally diffused. Most of them received instruction from the centaur Chiron. From him Hercules is said to have obtained his knowledge of physic, in which he was no less expert than in deeds of arms.

The practice of the Greek physicians, notwithstanding the praises of their poets, appears to have been very limited, and often pernicious. A great many of their remedies consisted of charms, incantations, amulets, &c. In this way, then, medicine continued for many ages. Its first professors were ignorant of anatomy, and knew as little of the theory of diseases. It is plain therefore that whatever they did was mere random trials, or empiricism, in the strict and proper sense of the word. Among the Greeks, however, Æsculapius was considered the most eminent practitioner of his time, and his name was revered after his death. He was ranked among the gods, and the principal knowledge of the art remained in his family to the time of Hippocrates, who was one of his descendants. This physician is justly considered as the father of medicine. From his time, medicine, separated from religion and metaphysics, seems to have assumed the form of a science, and to be adopted as a profession. After the days of Hippocrates, the science gradually improved through other physicians, particularly Proxagoras, Eristratus, and Herophilus. The first physician of eminence who greatly differed from Hippocrates was Proxagoras; the next is Eristratus, who was a man of great talent, and flourished in the time of Seleneus. He was instructed by Chrysippus, who prohibited the use of aperients, emetics, and lavements; and, according to Galen, he banished venesection or bleeding from his practice. Others, however, affirm that he did not totally discard, but only employed it less frequently than his contemporaries. Herophilus was the first who properly knew the doctrine of the pulses, of which Hippocrates possessed but little knowledge—a branch of medical science of such vast importance that Dr. Rucco has published two large volumes replete with practical information on the subject. Herophilus also noticed the disease now known by the name of *anguina pectoris*, but which he called palsy of the heart; and to this it was that he ascribed certain hidden deaths. According to Celsus, medicine was at this period divided into three branches, viz. the dietetic, pharmaceutical, and chirurgical medicine. The first of these employed a proper regimen in the cure of diseases; the second, medicines as remedial agents; and the third, the operation of the hands; and from this time we may date the division of practitioners into physicians, apothecaries, and surgeons. Previous to this period, the physician performed all the duties of the other two classes.

Avicenna, who was born A.D. 1078, placed Arabian medicine at its height, and for a considerable length of time superseded the doctrines of Galen, which however ultimately revived. The cultivation of medicine in the western parts of the world commenced at Salerno, perhaps as early as the ninth century, but in 1143 and 1233 was finally established; and here medicine was taught according to the principles of the Greeks. The Galeno-Arabian science of medicine, which flourished during the middle ages, was mostly fostered by the monks, and only existed through ignorance and superstition. Mundinus, in the fourteenth century, by improving the study of anatomy, caused that of medicine to be better cultivated; and he describes the discovery of several new remedies, both foreign and domestic. The study of Greek literature was revived by the scholars who were driven from Greece by

the conquest of Constantinople in 1453, when the Greek medical writings were read in their original language, particularly Hippocrates. This caused a more scientific and liberal spirit of investigation to take the place of antiquated prejudices. Thus the ultimate fall of the Galenic system was prepared and completed in the sixteenth century, and forms the most essential part of the reformation accomplished by Paracelsus in 1526. The chemico-theosophical system of this enthusiast was refined and arranged by Van Helmont, who died in 1644, until deprived of its theosophical character it passed over into the chemico-material system of Franciscus Sylvius, who flourished about 1660, and at length into the peculiar views of Stahl. Dr. Frederick Hoffman methodized, if he did not originate, the dynamic system, from which all the dynamic schools of modern times have proceeded. The newest systems are those of M. Broussais, who traces all diseases to inflammation of the bowels, and of Dr. Samuel Hahneman, who denominates his doctrine homœopathy, the essential characters of which are that such remedies should be employed against any disease as in a healthy person would produce a similar but not precisely the same disease, and in the conviction that every malady carries with it a great susceptibility for the proper medicine, and that the power of medicine increases by minute division. The homœopathist gives but one drug at a time, and does not administer another dose of a new medicine until the first has taken effect; at the same time, a strict diet is prescribed, that the operation of the medicine shall not be disturbed. In the preceding sketch we have of course omitted all reference to the modern medical writers, as a bare enumeration of the titles of their works would form an extensive catalogue. But the labours of Cullen and Mason Goode have fortunately brought into one focus nearly the whole of modern medical science.

Surgery is that branch of the healing art which cures or prevents diseases by the application of the hand. War early made the healing of wounds more important than the curing of diseases, which were then less frequent, on account of the simple manner of living. In the time of Hippocrates, lithotomy was forbidden to be performed by the physicians. The Arabians likewise felt an aversion to operations, and it was considered beneath the dignity of the physicians to operate themselves. In the middle ages, the practice of the healing art was almost entirely confined to the priests and monks. But in 1163 the Council of Tours prohibited the clergy, who then shared with the Jews the practice of medicine in Christian Europe, from performing any bloody operation. Surgery was banished from the universities under the pretext that the church detested all bloodshed; consequently the useful sciences of medicine and surgery became separated from each other. The separation was the more easily effected since the bath-keepers and barbers had undertaken the practice of surgery. In France the company of barbers was formed in 1096, when William, then archbishop of Rouen, prohibited the wearing of the beard. These bath-keepers and barbers remained for several centuries in possession of the practice of surgery. Meanwhile the mists of the middle ages gradually disappeared. Enlightened by the science of anatomy, surgery began to assume a new and brilliant position, and the productions of Berengario de' Carpi, of Fallopius, of Eustachius, &c., were the true sources of knowledge from whence Ambrose Paré enriched this science, which had been previously degraded by its unison with the trade of a barber, but in this country the appellation of barber-surgeon continued until the establishment of the Royal College of Surgeons by charter, granted by George III., when this unscientific union was dissolved. By the important discoveries of Fabricius, Wiseman, and Dr. William Harvey, surgery made a very rapid progress. In 1731 the Academy of Surgery was established in France, and soon became celebrated throughout Europe. The Maréchal la Peyronie, Lamartiniere, &c., were distinguished surgeons. The collection of memoirs and prize writings of this academy contains the history of this flourishing period. There are preserved the labours of I. L. Petit, Lafage, Le Cat, Sabatier, and many other eminent practitioners. At this period flourished in Ger-

many and the north of Europe Heister, Zach, Platner, Roderer, Theder, and Richter. In Holland, Albinus, Deventer, and Camper; in Italy, Molinelli and Moscati; in Great Britain, Cheselden, who was celebrated as a successful lithotomist, Douglas, the two Munros, Sharp, Alanson, Smellie and Percival Pott of St. Bartholomew's Hospital, Cline, and Abernethy. At the present day we have, besides Sir William Blizard, who has justly been considered as the father of modern surgery, Sir Astley Cooper, Sir Benjamin Brodie, Mr. Lawrence, Mr. Guthrie, and Sir Charles Bell, and many of these gentlemen are the authors of productions that are a credit to the age we live in. Our space does not permit of our pursuing the subject further; but it must be obvious that now surgery goes hand in hand with medicine, and is supported by minute anatomical knowledge, it must advance rapidly towards perfection.

Chemistry is the handmaid of medicine no less than the domestic arts; a brief history of the progress of this branch of knowledge is therefore essential to the plan we have sketched out. Chemical research is indeed a most delightful employment; and, as we have already had occasion to state, it in no shape involves the necessity of purchasing costly apparatus. Experimental data perfectly illustrative of the science may be procured by the simplest means, and with almost as much certainty as in the various branches of mechanical science. In this respect the moderns enjoy amazing advantages over the ancient alchemists. They laboured with a degree of incertitude equalled only by the followers of the occult art, and at a period when sober utilitarian science would have had but few followers. But, however vague and visionary we may consider the labours of the early alchemists, they certainly have the merit of having invented much of the chemical apparatus we now employ. To render our sketch, therefore, of the history of chemistry intelligible to the reader, it will be necessary for us to trace somewhat in detail the labours of these amusing visionaries.

Passing by the first dawn of alchemy, which evidently commenced at a very early period, we find the art formed into a regular code of knowledge, under the patronage of the Gothic king Alonzo. In the *Libro del Tesora*, written by that monarch, he states, with an appearance of great devotion and humility, that, although he had not wished for the philosopher's stone, yet the gift was bestowed upon him, that he might defend the kingdoms of his fathers. "In secrecy," he says, "I was instructed in this inestimable treasure, and therewith did I increase my wealth." It would have been fortunate if he could have employed this power in the season of distress; for letters are extant in which king Alonzo solicits alms; and at a prior period he actually pawned his crown jewels to the governor of Morocco. The fancied treasure of Alonzo was guarded with much jealousy. A copy is extant in the royal library of Madrid, bound in boards of massy oak. The manuscript was locked with an iron lock, a circumstance from whence it also obtained the name of the *Libro del Candado*. This precaution, however, seems to have been needless; for all the efficient lessons of the art were written in secret characters, so that the opening of the volume is of little service, even to the "good and the wise," for whose profit Alonzo wishes to reserve the exposition of the secret, which he was also equally anxious to conceal from the profane. The cipher employed by Alonzo indicates the source of his knowledge. His alphabet appears to be a current Cuphic character, or rather that modification of the Cuphic which is still used by the Occidental or Mauritanian Arabs, but the letters are varied by points and flourishes; they are probably not employed according to their original powers; and it appears from the table or key at the end of the Madrid manuscript that each letter of the Roman alphabet has ten or twelve corresponding signs in the secret character.*

*By the common consent of the ancient writers we are taught to consider Egypt as the parent land of alchemical science. Perhaps some of the numerous symbols which the astronomer employed in common with the alchemist, if not truly Egyptian hieroglyphics, may at least be reminiscences or imitations of the sacred character. The signs denoting the seven planets are unquestionably of high antiquity, and figures

In the thirteenth century, Albertus Magnus, Roger Bacon, and Raymond Lully, seem to have been the great stars of alchemy, which they raised to a degree of credit somewhat beyond its merits. The alchemists, however, still endeavoured to veil the terms as well as the principles of their art under mystical characters. That the alchemist possessed a certain portion of useful knowledge cannot be doubted. Mr. Brande, who has ably traced the history of chemistry from its rude and expirical origin until the present era, says that the works ascribed to Geber contain matter that well justifies the praise of Boerhaave, who considers him as a first-rate philosopher of his age. But the secrecy which the alchemists affected repelled improvement, and almost every discovery died with its inventor. Until the "Triumphant Chariot of Antimony" rolled forth, and the bold but credulous physicians of the sixteenth and seventeenth centuries borrowed the powerful materia medica which they found in the laboratory, by which they discomfited the followers of Galen, the chemistry of Hermes had scarce produced any practical benefit in the higher pursuits of science, and the assistance which some of its preparations afforded to a few branches of the arts was accomplished rather by accident than by intention." Mr. Brande observes that "the transmutation of baser metals into gold and silver, which was the chief, and, in most cases, the only object of the genuine alchemists, was not merely regarded as possible, but believed to have been performed, by some of the more enlightened chemists of the seventeenth century; and in perusing the history of these transmutations as recorded by Helvetius, Boerhaave, Boyle, and other sober-minded men, it would be difficult to resist the evidence adduced without the aid of modern science. Lord Bacon's sound sense has been arraigned for his belief in alchemy, although he in fact rather urges the possibility than the probability of transmutation; and, considering the infant state of the experimental sciences, and of chemistry in particular, in his age, and the plausible exterior of the phenomena that the chemists were able to produce, he is rather to be considered as sceptical then credulous upon many of the points which he discusses. Some of the narratives of the effects of transmutation are indeed of a most extraordinary character. Helvetius positively affirms that he converted half an ounce of lead into pure gold, the materials for which were furnished him by an artist named Elias. The alchemist who arranged the process is said to have been absent when the experiment was made, which however succeeded so perfectly that the precious metal made from the lead was worth twenty-five florins.

Frederick III., emperor of Germany, is said to have caused a medal to be struck of the gold produced by an alchemical operation, which was performed in his presence by an alchemist of the name of Richterhausen. Frederick was so well satisfied with the result that he granted letters of nobility to the adept, and called him up amongst the barons of the Holy Roman Empire by the appropriate style of "Baron of Chaos." Such a fief was worth a fortune, and accordingly, wherever he went, the baron of Chaos met with capital success. At the court of the elector of Mayence he offered to effect a transmutation, for which purpose he produced a small portion of the matter of projection, in size and shape like a lentil. The powder had been mixed up with gum tragacanth, for the purpose, as he said, of binding it, and then again the pellet was enveloped in wax. The elector was desired to put it, together with four ounces of quicksilver, in a crucible, which was afterwards covered with charcoal. The elector and the

resembling them, though they may not bear the same signification, are found on Egyptian monuments. Alchemical symbols are discovered in the sacred edifices of the middle ages; and their appearance need not excite surprise, notwithstanding the seeming incongruity of their position, as alchemy was then considered the most pure and holy art vouchsafed to man by the benignity of Providence. It was a favourite study of the clergy; and a numerous and venerable cohort of adepts might be assembled from the cloister and the cathedral. The consecrated walls and the storied window have displayed the symbols of the magistery and the elixir; and the blue lion and green lion, the red man and the white woman, the toad, the crow, the dragon, and the panther, all alchemical signs, were blended with the legends of the saints and martyrs.

baron of Chaos then blew the fire vigorously, and at the expiration of half an hour the crucible was taken from the furnace, and the baron poured out the molten gold. The liquid metal appeared of a bright red, and the baron exclaimed that its touch was too high—it must be lowered by the addition of silver. The elector threw in a bar of silver, and after a second fusion the metal was cast in an ingot. It was very pure, but rather brittle. The baron of Chaos easily accounted for this defect, as he said that "some particles of tin had probably adhered to the ingot mould, but a third fusion would remove the alloy." This was done at the mint, and the gold then became exceedingly ductile, and the mint-master told his serene highness "that he had never seen such fine gold, and that its touch was more than twenty-four carats." Monconnis tells the story in the words of the elector, and it is evident that both of them believed that a real transmutation had actually taken place.

Less fortunate than the baron of Chaos was an alchemist of the name of John Henry Muller, who originally practised as a barber in Alsace, his native province. The court of the emperor Rodolph, a munificent patron of the occult sciences, offered great temptations to adventurers of this description, and Muller's management of the emperor was so satisfactory that he obtained large presents. He was exalted into the caste of nobility, and his humble surname of Muller, or Miller, was judiciously expanded into the title of "Baron of Muhlenfels." After may adventures, the baron arrived at Stuttgard. Duke Frederick of Wirtemburg was as ardent an alchemist as the emperor, and the baron performed many transmutations with great success. The duke poured the metals into the crucible, the doors of the laboratory were locked and sealed, and on the following morning the amalgam of lead and mercury was found richly impregnated with gold. Another operation performed in the castle of Reidlingen had the same result. It appears that the baron of Muhlenfels was enabled to effect the first transmutation by the help of a confederate concealed in a chest which was supposed to contain chemical apparatus; and at Reidlingen the same useful agent found his way through a vault. But the baron was not allowed to enjoy his credit in peace; for now the far-famed Sandivogius made his appearance at Stuttgard. He was really a Polish nobleman, and universally considered as the greatest alchemist and magician of the age. The two adepts were placed in a dramatic situation, which would be ludicrous enough were it not for the catastrophe. The baron of Muhlenfels was a credulous rogue, and, conscious that he was an impostor, he was dreadfully perplexed by the presence of a rival whom he verily believed to be a true master of the occult sciences. By insinuating to Sandivogius (whose conscience was probably not very clear, and who seems to have been equally apprehensive of coming in contact with any genuine sage) that the duke intended to put him to the torture for the purpose of obtaining the secret, the baron induced him to run away from Stuttgard. Muhlenfels then contrived to arrest the adept on his road, by virtue of a feigned order. Sandivogius was thrown into a dungeon by a village judge, and Muhlenfels took possession of his property, which was very considerable. The unlucky alchemist was nearly killed by the severities which the false brother inflicted upon him, in order to compel him to disclose the mysteries of the art; for, as we have observed before, Muhlenfels never doubted but that Sandivogius possessed the philosopher's stone. Sandivogius at length escaped from his prison, and accused the baron before the imperial tribunal; and Muhlenfels was found guilty of robbery, and condemned to die.

The old jurists had some difficulty in determining whether it was lawfully allowable to make money by alchemy. Baldus, a high authority amongst the civilians, gave his opinion that the practice was legal. Our common lawyers thought otherwise, and in the reign of Henry VI. an act was passed (according to lord Coke it is the shortest in the statute book) which ordains "that no one from henceforth shall use to *multiply* gold or silver, nor the craft of multiplication." Boyle is said to have procured the repeal of the prohibitory enactment,

on account of the impediments which it offered to the study of alchemy; but, by inspecting the petition upon which the act was founded, it appears that it was intended merely to repress the ingenuity of a most unphilosophical class of artists. The commons prayed that the practisers of the aforesaid art should, upon conviction, incur the punishment of felony; "because many persons, by colour of this multiplication, make false money, to the great discredit of the king, and the injury of his people."

It might be thought that the number who had lost their all in this absurd and visionary pursuit would have induced more correct and scientific views. Yet alchemy stood its ground and flourished; and the adept, though a felon by act of parliament, worked in peace, with unchanged hope and unwearied earnestness. All the sad experience which he obtained could never suffice for his instruction. Retorts burst, and crucibles are shivered in the process,—the alchemist's projection evaporates in smoke and fume; but the adept is not to be roused from his day-dream. Again he returns to the laboratory. He refils the alembic and the aludel; and the "Bath of Mary" is replenished anew. Salt, sulphur, and mercury are blended in proportionate measure, and once more the parched disciple of Geber watches the concoction of the tincture and the menstruum, whilst he nourishes the slow reverberating flames of the furnace. His diligence abates not with increasing age. Years roll on. The colours of the liquid change; it reflects the azure line, which gradually softens into the play of the opal, and at length the iridescent tints concentrate into the gleam of the orient ruby. Breathless and feverish, he hails the appearances which the mystic sages of the east have taught him to consider as the tokens that the great work is fast approaching to its consummation. He rejoices, and expects that his toils are about to terminate and the elixir is in his power. But at the very moment of joy he discovers again that fate denies the boon: and the transmutation is as ineffectual as when, young in spirit and in years, he first read the perplexed allegories in which he has so long placed his trust.

While the alchemist was thus deceiving himself, and by his example tending to lure others into the same visionary track, he was in reality most materially benefiting the cause of chemical science. The furnace of the adept was nearly identical with that of the chemist in the present day. The retorts, crucibles, and other instruments for manipulating in connection with the furnace were also similar in their character; and, though alchemists wanted the metal platinum for very high temperatures, their vessels must have possessed great power of resisting heat, as there are well recorded instances of their enduring the action of fire for many years without intermission.

The preparatory essays of the alchemist lead us to the history of chemistry, properly so called. This cannot be said to have existed as a science previous to the commencement of the seventeenth century. Its general principles may be acquired from the ordinary phenomena of nature as they exist around us; and it is truly extraordinary that so many persons, not uninformed in other respects, should remain ignorant of the constitution of bodies upon which their very existence may be said to depend. And it is but too true that even at the present moment there are numbers who have, generally speaking, received a liberal education, that still consider earth, air, fire, and water as the only elementary bodies.

The names of Bacon, Boyle, and Hooke stand foremost in the list of the early cultivators of chemistry. The last of these writers, in his *Micographia*, published in 1664, has sketched a beautiful theory of combustion, in which he dwells chiefly upon the influence and necessity of air to the process, and refers the power of supporting combustion to a principle existing in saltpetre. The following are the principal passages relating to this subject:—"From the experiment of charring of coals (whereby we see that, notwithstanding the great heat, and the duration of it, the solid parts of the wood remain, whilst they are preserved from the free action of the air, undissipated) we may learn

that which has not, that I know of, been published or hinted at, nay, not so much as thought of, by any; and that, in short, is this :—First, that the air in which we live, move, and breathe, and which encompasses very many, and cherishes most bodies it encompasses, that this air is the menstruum, or universal dissolvent of all sulphurous bodies. Secondly, that this action it performs not, till the body be first sufficiently heated, as we find it requisite also to the dissolution of many other bodies by several other menstruums. Thirdly, that this action of dissolution produces or generates a very great heat, and that which we call fire; and this is common also to many dissolutions of other bodies, made by menstruums, of which I could give multitudes of instances. Fourthly, that this action is performed with so much violence, and does so minutely act, and rapidly agitate the smallest parts of the combustible matter, that it produces, in the diaphanous medium of the air, the action or pulse of light; which what it is I have elsewhere already shown. Fifthly, that the dissolution of sulphureous bodies is made by a substance inherent, and mixed with the air, that is like, if not the very same, with that which is fixed in saltpetre, which, by multitudes of experiments that may be made with saltpetre, will, I think, most evidently be demonstrated."

Mayow, in 1674, appears to have thrown out a suggestion tending to show the existence of vital air as an agent in the process of combustion. Newton, to whom every branch of science owes a deep obligation, made two important contributions to chemistry. He subverted the ancient doctrine concerning the causes of chemicalaffinity; and, instead of referring the tendencies which bodies have to combine to the peculiar forms and attributes of their atoms, he referred it simply to the attractions belonging to their ultimate particles. His queries on this subject attached to his work on optics are so explicit and distinct as to be creditable even to the sagacity of Newton. To him we are also indebted for the discovery of a mode of graduating thermometers, so as to render them correspondent with each other; this was that real utility conferred upon the instrument, by which philosophers were afterwards enabled to carry on their researches in a very difficult department of chemistry with remarkable facility and precision.

In France, about the same period, we find Geoffroy, the two Lemerys, and Homberg, actively engaged in experimental pursuits. The last of these chemists is well known as the discoverer of pyrophorus. Beccher allowed the existence of five elementary substances: water, air, and a vitrifiable, an inflammable, and a mercurial earth; he considered acids as derived from the union of earth and water; stones as produced by the combination of two earths; and metals by the combination of the three earths in variable proportions. Beccher also added to the instruments of chemical research, and simplified many of the very complex operations then prevalent in the laboratory. As a practical chemist he is perfectly intelligible, but his theories are involved in so much contradiction and mystery that it is barely possible to understand the ends he aims at. He was succeeded by Stahl, whose name, as coupled with the once prevailing and generally received phlogistic theory, is familiar to chemists. Stahl's doctrines are perspicuously set forth in his *Fundamenta Chemicæ*, published at Nuremberg in 1723. He refers combustion to the separation of a highly subtile and elastic matter, which, under certain circumstances, is thrown into violent agitation, and then constitutes flame or fire: this principle he terms *phlogiston*. He asserts that when substances are burned they throw off *phlogiston*, and that, by its addition to the residuary matter, the original substance is reproduced; and endeavours to demonstrate this assertion by reference to the combustion of sulphur and some of the metals.

The discoveries of Dr. Black come next in order; and, whether with reference to their own value or their immediate influence upon other branches of chemistry, may be considered as forming an era in the science. His first experiments refer to the causticity of the earths and alkalies. It was long known that chalk, which is a mild insipid substance, after having been

made red hot, became converted into quick-lime, which is caustic and acrid; but the cause of this change, though it had been looked for by Macquer and others, remained unknown; it was generally referred to the absorption of fire. Black's attention was drawn to this subject by the discovery of magnesia, which, in 1720, was first distinguished from lime by the celebrated Hoffman, who also obtained it from sea-water. Dr. Black's researches led him to ascertain the existence of a peculiar aëriform matter in the mild earths and alkalies, which was driven off by heat and expelled by acids, and which he called *fixed air*.* But the enquiries which have generally been considered as the main foundation of Dr. Black's scientific eminence are those relating to the operation of heat in changing the states of bodies, as in converting solids into liquids and liquids into vapours.

Dr. Priestley's first written contribution to the cause of chemical science appeared in 1771; and two years later he fully explained the influence of vegetables upon the purity of the atmosphere. †

In 1774 Dr. Priestley procured oxygen gas from red lead. This he called "dephlogisticated air;" he also discovered several other gases. Five years afterwards, Bergman published his *Opuscula*, containing a variety of important essays on chemical subjects. He was succeeded by Scheele, who exhibited the results of a series of experiments on air and fire. Scheele discovered baryta, and ascertained the existence of nitrogen in ammonia; he also pointed out the mode of obtaining several acid bodies. Cavendish was the first who obtained hydrogen in its pure state; and, combining that gas with oxygen, he was enabled to produce a definite quantity of water. He also showed the constituents of nitric acid. About this period Lavoisier gave importance to the French school by the publication of his antiphlogistic theory. He endeavoured to prove that oxygen was of necessity present in every case of combustion. This doctrine, however, we now know to be erroneous. Guyton, Morveau, and Fourcroy, assisted him in his experimental investigations, and by their united labours materially improved the system of chemical nomenclature. We now arrive at a brilliant period in the history of chemistry. The labours of Sir Humphry Davy, Thomson, Ure, Henry, Leslie, Dalton, Wollaston, Brande, Philips, and Faraday, omitting the discoveries of the modern foreign chemists, would alone form a series of volumes; and we must content ourselves with a reference to the results of their labours as they are detailed in the various articles in the subsequent pages of this Cyclopædia.

A branch of chemistry which the French have altogether raised to the rank of a science, and which in this point of view is in a great measure their own, is *crystallography*. They were not indeed the first who discovered the tendency of certain minerals always to assume regular forms; but Romé de Lisle, and infinitely more the abbé Haüy, have deduced from this property such an admirable series of laws, and so beautiful a system of nature, that any

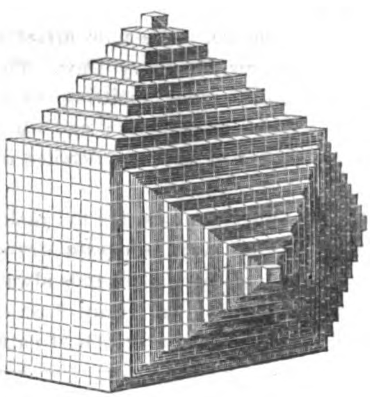
* It is a curious circumstance that Dr. Brownrig, in 1765, appears to have possessed a tolerable acquaintance with the nature of the choke-damp of the miners, as, in a paper read before the Royal Society, he pointed out the analogy which subsisted between that gas and the subtile principle of mineral waters.

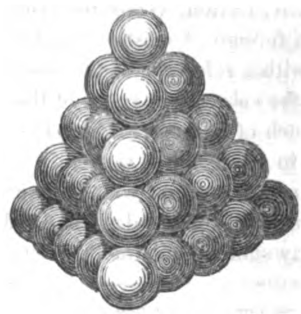
† The Royal Society voted Dr. Priestley the Copley medal for his paper on different kinds of air, read before the members; and the learned president thus illustrated one branch of the Doctor's observations:—"From these discoveries we are assured that no vegetable grows in vain, but that, from the oak of the forest to the grass of the field, every individual plant is serviceable to mankind, if not always distinguished by some private virtue, yet making a part of the whole which cleanses and purifies our atmosphere. In this the fragrant rose and deadly nightshade co-operate; nor are the herbage nor the woods that flourish in the most remote and unpeopled regions unprofitable to us, nor we to them, considering how constantly the winds convey to them our vitiated air, for our relief and for their nourishment. And, if ever these salutary gales rise to storms and hurricanes, let us still trace and revere the ways of a benificent Being, who, not in wrath, but in mercy, thus shakes the water and the air together, to bury in the deep those putrid and pestilential effluvia which the vegetables on the face of the earth had been insufficient to consume."

previous knowledge which others may have had of the more leading facts does not in the least diminish the credit of their discoveries.

It is commonly observed that crystalline bodies affect one form in preference to others. The fluor spar of Derbyshire crystallizes in cubes: so does common salt. Nitre assumes the form of a six-sided prism, and sulphate of magnesia that of a four-sided prism. These forms are liable to vary. Fluor spar and salt crystallize sometimes in the form of octohedra, and there are so many forms of carbonate of lime that it is difficult to select that which most commonly occurs. Romé de Lisle referred these variations of form to certain truncations of an invariable primitive nucleus; and Gahn afterwards observed that when a piece of calcareous spar was carefully broken all its particles were of a rhomboidal figure. This induced Bergman to suspect the existence of a primitive nucleus in all crystalline bodies. When Haüy entered this field of enquiry, he not only corroborated the opinions of Bergman, and submitted former hypotheses to experimental proof, but traced with much success the laws of crystallization, and pointed out the modes of transition from primitive to secondary figures. If we attempt to split a cube of fluor spar with the blade of a knife, assisted by a hammer, it will only yield with facility in the direction of the solid angles; and, pursuing the division in these directions, an octohedron will be the resulting figure.

Haüy obtained six primitive forms, which by further mechanical analysis may be reduced to three integral elements. The secondary forms are supposed to arise from decrements of particles taking place on different portions of the primitive forms. Thus a cube, having a series of decreasing layers of cubic particles upon each of its six faces, will become a dodecahedron if the decrement be upon the edges, but an octohedron if upon the angles; and by irregular, intermediate, and mixed decrements, an infinite variety of secondary forms will ensue, one example of which is given in the first of the accompanying figures.





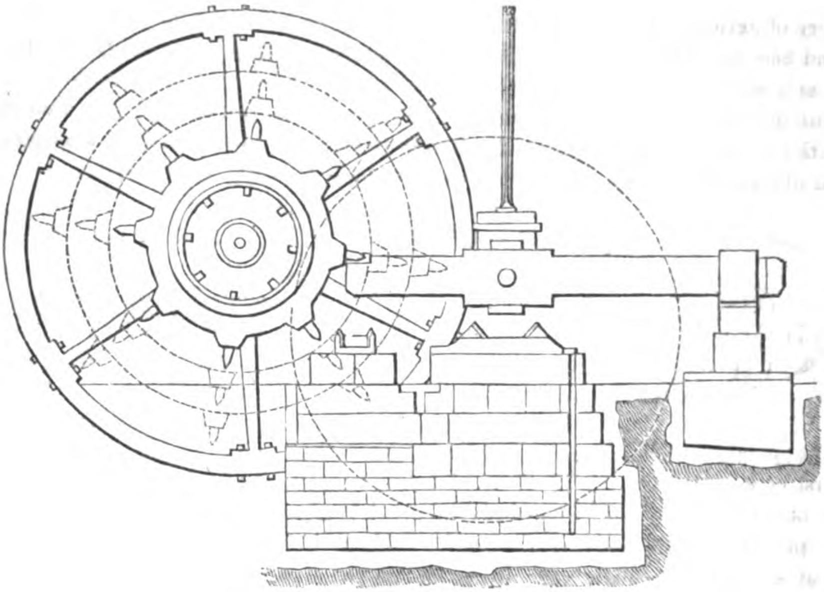
In crystallography we meet with appearances which Haüy's theory but imperfectly explains: a slice of fluor spar, for instance, obtained by making two successive and parallel sections, may be divided into acute rhomboids; but these are not the primitive form of the spar, because, by the removal of a tetrahedron from each extremity of the rhomboid, an octohedron is obtained. Thus, as the whole mass of fluor may be divided into tetrahedra and octohedra, it becomes a question which of these forms is to be called primitive, especially as neither of them can fill space without leaving vacuities, nor can they produce any arrangement sufficiently stable to form the basis of a permanent crystal. To obviate this incongruity, Dr. Wollaston very ingeniously proposed to consider the primitive particles as spheres, which, by mutual attraction, have assumed the arrangement which brings them as near as possible to each other. When a number of similar balls are pressed together in the same plane, they

form equilateral triangles with each other; and if balls so placed were cemented together, and afterwards broken asunder, the straight lines in which they would be disposed to separate would form angles of 60° with each other. A single ball, placed any where on this stratum, would touch three of the lower balls, and the planes touching their surfaces would then include a regular tetrahedron. An example of this simple and beautiful theory is exhibited in the right-hand figure on the previous page.

The working of *metals* is a strictly chemical art. According to Moses, it was known before the deluge. But that dreadful calamity deprived the greater part of mankind of this as well as other arts useful to life. It was not long, however, after this period, till some metals, at least, were known to the eastern nations; for in the days of Abraham they seem to have been common in Egypt, and several countries of Asia. In many parts of the world the precious metals, and especially gold, may be found without the necessity of digging into the bowels of the earth. Torrents pouring down from the mountains deposit great quantities of gold in the beds of brooks and rivers. The ancients speak of several rivers famous for rolling down gold, silver, copper, and even tin, in their waters; and we still know of certain streams which enjoy this advantage. Gold is found in this way not only in grains, but in masses of considerable bulk. In Peru pieces of nearly pure gold have been found, some of which weighed more than an ounce, and in Africa we have instances of natural ingots of a still larger size.

Even when men came afterwards to dig for metals in mines, they would at first find little difficulty in refining them; for on the tops of mines metals are commonly found quite pure, or with very little foreign admixture. At the discovery of the celebrated mine at Potosi, we are told that the vein was so rich that the metal appeared elevated like a rock above ground. According to Acosta, it was a kind of ridge upon the top of a mountain, 300 feet in length, and thirty in breadth. "In the mine of Salcedo," says Ulloa, "they at first found lumps of silver, which gave them no further trouble than to cut them with a chisel; and on the mountain Ucuntaya there was discovered, in the year 1713, a prodigious crust of solid silver, which yielded several millions of dollars." In Hudson's Bay there is a mine of red copper, so rich and pure that without using fire, and only by beating it between two stones, the inhabitants are enabled to form it into all kinds of utensils that they have occasion for. It is reasonable to judge of the ancient mines by these specimens of the metallic treasures of modern countries which are but little frequented; and, when we consider these facts, we shall not be greatly surprised at the abundance of implements of metal in very remote times. Copper is a metal of great tenacity and considerable hardness: so that it furnishes a material not unfit for the fabrication of workmen's tools, and cutting instruments. The swords, hatchets, and daggers, of very ancient nations were of copper, either pure or mixed with tin, by which its hardness is considerably increased. But copper is very inferior as a material for sharp-edged instruments to iron, which may be made by certain processes to cut the hardest substances, and to retain its edge for a long time. Iron, however, is by no means easily disengaged from its ore, and is hardly ever found natural in its metallic state. To convert the ore of iron into metal, it must be pounded and washed, and smelted by intense heat more than once, and in contact with charcoal, or some substance capable of reviving it from the state of dross; and, to form it into steel, still more complicated processes are necessary, and nearly all these manipulations require the labour of the chemist for their first invention. Iron forms the great source of our commercial wealth, and those who have only seen the vast sledge whirled by human arms can have but little notion of the giant powers of the tilt hammer when put in motion by machinery. Hammers weighing many hundred weight carry on their unvaried course as though their ponderous arms possessed the miraculous powers ascribed to Briarius in the olden time. They

are sometimes impelled by water and at other times by steam; but in all cases they are provided with a large fly-wheel to equalise their motion, as in the accompanying engraving.

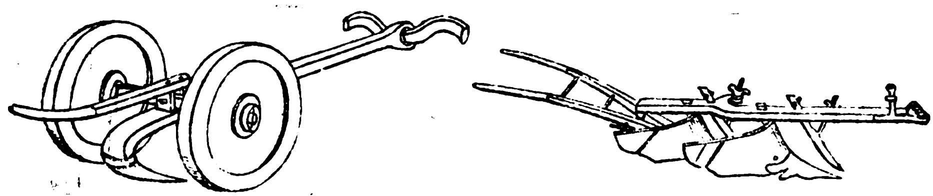


The mass of iron forming a tilt hammer is now supported on a large beam, somewhat similar to a scale-beam, and a strong axis passes through the beam, on which it works as a fulcrum. The projecting pegs are made to depress the one extremity, which of course tends to elevate the opposite end; and the momentum which it acquires in its subsequent descent presses on the iron and moulds it into the required form.

Although all the metals are skilfully worked by English artificers, yet it is most remarkable that those in which they excel are the most refractory; those which, when dug out of the earth, have the smallest importance, but to which thought and labour give the highest utility; those on which the hand of man, directed by his genius, accumulates the greatest factitious value; that is to say, a value which is nearly null in the savage state, but which goes on increasing in the exact ratio of intellectual civilization. The French, on the contrary, have turned their attention to the metals which have the greatest value in themselves, and to which, when wrought, the workmanship adds the smallest merit. Thus jewellery has long been a favourite manufacture with them, as well as the fabrication of the precious metals in all their shapes. These are the most luxurious and the least useful of the metallurgic arts; they are the least intellectual also, as gold and silver are more easily purified and melted than iron. Necessitous nations have, indeed, fabricated jewellery, but not until more urgent wants had been satisfied, and previous exertions had brought home the wealth which in some measure entitles man to indulgence. Some nations, too, whose demand for domestic consumption was small, yet fabricated them for the gratification of others: thus anciently did Tyre and Sidon. Thus Venice and the Netherlands have at different times been celebrated for their gold and silver works, but only when the immediate necessities of those republics had been satisfied, only when other objects more useful had been produced both for the home and the foreign market; and the woollen cloths of Bruges were some centuries earlier than the plate and jewellery of the same city.

Agriculture owes almost all its present improvements to the science of chemistry. It is true that many ingenious mechanical contrivances have been suggested by the mere tiller

of the earth, and by this means the labour of the husbandman considerably abridged. But the real character of the various soils, which must form the basis of all theoretical agriculture, was scarcely at all developed prior to the close of the last century. It is indeed to the discovery of agriculture that we owe a large portion of the arts and sciences. As long as mankind had no other way of subsisting but by hunting, fishing, and feeding their flocks, the useful arts made but little progress; and those nations who do not practice agriculture have still but a very slender acquaintance with the arts and sciences. We cannot better illustrate the past and present states of agriculture than by taking one of the most elementary of agricultural instruments, and comparing its modern with its ancient form.

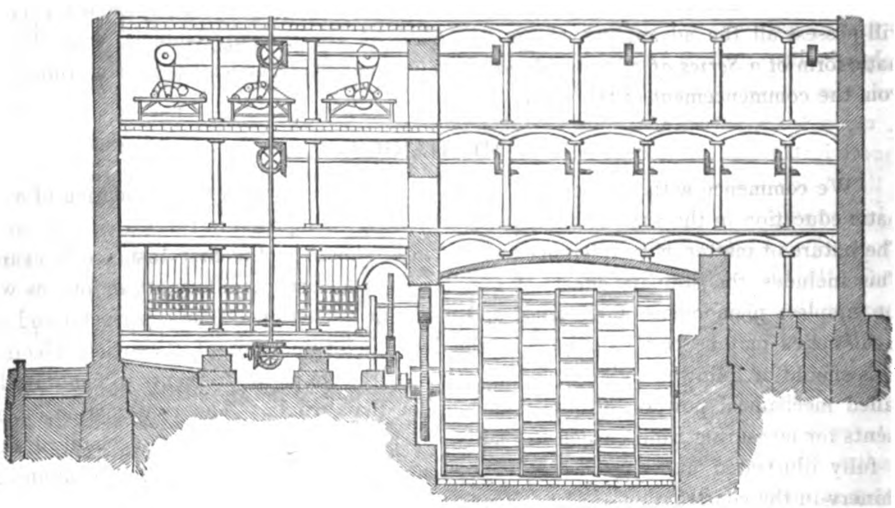


The plough, as it was employed by the Roman agriculturist above 2000 years ago, may first be adverted to. It will be seen by a reference to the above sketch that it consisted merely of a hook, which had no way of clearing itself of the soil through which it was impelled, sometimes by the labour of men and at other times by animal power. It did not, in fact, cut a track through the earth, but tore a groove in the soil. Let us contrast this primeval instrument with lord Somerville's double-furrow plough, and we shall then find that the chemical and mechanical construction of the apparatus is strikingly dissimilar to the one just examined. Chemically speaking, air is essential to the existence of vegetable life: the root serves to attach the plant to the soil, and is one of its organs of nutriment. Now, to enable the root to shoot freely, the earth must in the first instance be broken up and then exposed to the action of the atmosphere. This is most effectually performed by the operation of the improved plough; for instead of the earth being raked or torn up, as in the former case, it is now cut in a series of slices, forming in some cases a single and in others a double furrow. The old mode of ploughing was in fact little more than the preparation of a series of grooves for the seed, and with little chemical advantage to the soil, which was afterwards necessitated to lie fallow for a considerable period of time. Indeed we find that though the presence of light, air, and moisture, aided by a due temperature, are necessary requisites for the growth of plants, yet they also derive considerable nutriment from the soil, which becomes impoverished by their growth, and ultimately incapable of supporting vegetation, unless aided by manures. Now it is to the chemist that we must look for the sort of manures best fitted for this purpose; and the agriculturist who seeks for information upon the subject cannot do better than consult Sir Humphry Davy's *Elements of Agricultural Chemistry*, which has formed the ground-work of all the subsequent treatises.

Our space does not permit of any detailed view of the useful arts, but there is one to which this country is so much indebted, and which owes so much of its excellence to the aids afforded by chemistry, that some notice appears essential. The history of the cotton manufacture alone would form a useful as well as an interesting volume, and it would serve to show from what comparatively insignificant sources first-rate cities, and even large districts, may become wealthy and influential. The art of weaving is of great antiquity, and appears even to have arrived at considerable perfection in the remotest ages. To do this it is not necessary to have recourse to very complicated machinery, as the inhabitants of the east at present weave very fine and beautiful stuffs with comparatively simple instruments. A shuttle, and a few small pieces of wood, are sufficient for their purpose.

It may not be improper to observe that, in ancient times, the work of weaving was performed in a standing posture. This is attested both by Homer and Virgil. The warp was extended perpendicularly from top to bottom, and kept firm by means of a piece of wood, to which heavy weights were appended. The Egyptians, it is said, were the first who changed this incommodious and fatiguing posture into that of sitting at the work as our weavers do at present. It is well known that it was women alone who originally spun, wove, and even dyed wool and cloth. Besides the materials for clothing furnished by the animal tribes, there are a variety of plants, such as cotton, flax, hemp, &c., which supply a substance exceedingly proper for this purpose. It probably would not be long before men began to manufacture cotton, as the seeds of this shrub are lodged in a kind of down, which has a great resemblance to fine wool, and requires but little preparation to render it fit for spinning. We may therefore conclude that cloth of cotton was a very ancient invention.

The early cotton weaver, placed before a loom of the simplest kind, could scarcely interlace more of the fabric he proposed to manufacture than would suffice for the wants of his own family. The water-wheel and steam-engine now, however, afford such admirable substitutes for animal power, that a single manufactory will supply enough cotton for a large city. One of these wholesale producing mills is exhibited in the subjoined engraving.



In this case water is the impelling power; the mountain stream, guided by the hand of human ingenuity, is made to strike against, and cause to revolve, the principal axis of the machine. Its power is then conveyed into a variety of channels, each putting in motion the machinery for one or two individuals. Here, then, the produce of the cotton plant is converted into a durable and beautiful fabric, frequently vieing in tints with those produced by the looms of Tyre in the olden time; whilst those fabrics which are intended to retain a glossy whiteness acquire that character by the agency of a chemical process in a few hours, though the old arrangement of bleaching required weeks, and in some cases months, of toilsome labour. In conclusion, it may be proper to state that the application of chemistry to the useful arts has been one of the primary objects in the following pages, which are intended as far as possible to familiarize science, by stripping it of those technicalities which serve rather to astonish and confound than to instruct the real enquirer after knowledge.

ANALYTICAL TABLE OF CONTENTS.

[The alphabetical form of arrangement necessarily adopted in all cyclopædical works has hitherto prevented their being employed as a means of systematic instruction. To remedy this inconvenience, we have prepared the following analytical table, in which we purpose pointing out, under each head, the most useful mode of studying the branches of science there classed together. It is obvious that by pursuing this plan the British Cyclopædia will possess all the advantages of an *Alphabetical Dictionary,* combined with the systematic form of a *Series of distinct Treatises,* an arrangement which has been a primary object from the commencement of the work.]

MECHANICS.

We commence with this science, as it should evidently form the foundation of a systematic education in the various branches of knowledge comprised in this division of our work. The nature of matter, with reference to *attraction,* should in the first instance be examined. This includes the ordinary effects of gravitation, cohesion, capillary attraction, as well as the simplest phenomena of electrical and magnetic attraction. The centripetal and centrifugal forces may be best examined in the introductory portion of the article Mechanics. This should be followed by an acquaintance with the simple instruments to facilitate labour called mechanical powers, also described under that article. The construction of instruments for measuring time, which in reality consist of a combination of mechanical powers, is fully illustrated under Clock, Watch, and Pendulum. The mode of combining machinery in the construction of Mill-Work should be succeeded by an examination of the theory of Wheel Carriages.

The mechanical properties of the atmosphere form an interesting branch of this subject. They are discussed under the articles Air, Atmosphere, and Pneumatics. The air-pump, which forms an important auxiliary to this branch of science, is illustrated with a plate under Pump. The elasticity of the air is shown under the article Air-Gun.

The phenomena of sound, which are mainly produced by the mechanical vibrations of the air, may now be examined with advantage. The articles Acoustics, Sound, Ear, and Wind-Instruments, contain all that is necessary under this head.

Having thus pointed out the sources by which an acquaintance may be acquired with the mechanical properties of the atmosphere, we may next proceed to apply them in the construction of the Barometer and the Water-Pump.

The nature of the fluidity of water, as well as its pressure, is described under Hydrostatics and Press; and the history of our acquaintance with its compressibility at page xxxv in the Introduction. The theory of Specific Gravities should also be carefully studied, and if possible experimentally illustrated. The motion of water, as well as its mechanical properties, is examined under Water-Wheel, Pumps, and Water-Ram, and its passage

through various sized orifices, under AJUTAGE. AEROSTATION, as a branch of hydrostatics, and the various mechanical contrivances for elevating and depressing balloons, will be found under AERONAUTICS.

The theory and construction of the STEAM-ENGINE may now be understood. Its history is given under that article, and its application to locomotive purposes is also treated of under CARRIAGE and RAIL-ROADS.

Mathematical investigations have been as much as possible avoided in discussing the subjects to which we have thus briefly adverted. The reader should, however, make himself perfectly acquainted with the articles ALGEBRA and GEOMETRY at the commencement of his mechanical studies, as they are essential to a right understanding of many of the articles which occur.

LIGHT, ELECTRICITY, AND MAGNETISM.

The phenomena at present known in connection with these sciences are so analogous as to render it necessary for them to be studied in conjunction. Some of the properties of Light, with reference to its natural effects, are discussed under that article, and should first be examined. The history of Optics, combined with the Introduction, exhibits a complete view of the progress of that science; and the articles Microscope, Micrometer, and Telescope, illustrate the present state of knowledge with reference to the construction of those optical instruments. The theory of the Burning-Glass and Burning-Mirror will be best understood by examining those articles in connection with Refraction and Reflection. The Rainbow and Polarization of Light, which are usually found difficult subjects to comprehend, may now be understood.

Electricity and magnetism are intimately connected with the previous subjects. After consulting the general articles Electricity, Galvanism, and Magnetism, their connection will be further illustrated under Electro-Magnetism, and Spectrum. The best forms of the Compass, and mode of constructing Professor Barlow's improved apparatus, will be found under that article and Magnetism.

ASTRONOMY.

The study of this branch of science may be best commenced with the articles Newtonian Philosophy and Attraction. The history of Astronomy should be followed by an acquaintance with the sizes and relative situations of the planetary bodies, and their satellites taken in detail; the phenomena of eclipses, and the causes of the tides, may also then be readily understood. The Seasons are beautifully illustrated by Mr. Christie's tellu-

rium, described under that article, and a knowledge of practical astronomy may be best acquired by a reference to the various instruments, as they occur in the work.

ANATOMY, MEDICINE, AND CHEMISTRY.

The history of these subjects, as well as physiology, pathology, &c., is given in the Introduction to this work; and our acquaintance with the structure of the human body must evidently be commenced with the articles ANATOMY, PHYSIOLOGY, MUSCLES, and NERVES. The study of the ATOMIC THEORY is an important part of Chemistry, and the student in this science will do well to make himself acquainted with the phenomena of light, heat, and electricity, preparatory to an examination of ponderable matter. OXYGEN, CHLORINE, and IODINE, will next come under his consideration, to be followed by the simple idifiable and inflammable substances. The metals, as well as the bodies which compose

the various animal and vegetable substances, will be found interspersed through the miscellaneous articles of the work.

FINE ARTS.

Painting and sculpture form the principal features of this division. The history of painting will be found under the article ARTS, FINE, and the principal styles of the art are illustrated under the general titles of BYZANTINE, ÆGINETAN, GERMAN, ITALIAN, and NETHERLANDS, STYLES. These should be read preparatory to the study of the technical parts of the subject, which are discussed under DRAWING, GROUPING, PAINTING, PORTRAITURE, and WATER-COLOURS. ENGRAVING forms a middle link between painting and SCULPTURE; the latter is discussed in the general articles SCULPTURE, ARTS, BASSO RELIEVO, GEM ENGRAVING, and DACTYLIOTHECA.

MUSIC holds the next rank in the fine arts. The general article must be consulted in connection with CHORD, CONCORD, CHORUS, NOTE, SINGING, SOLO, SOLFAING, TIME, TONE, and the various minor articles which occur.

HERALDRY is illustrated in that article, and the general terms occur in the miscellaneous articles dispersed through the work.

USEFUL ARTS.

This divison occupies a very wide range. ARCHITECTURE would properly belong to the preceding division; but, as it would separate the theoretical from the practical parts of building, it has been deemed advisable to keep the group of articles connected with architecture under the present head. The other branches of the useful arts require no particular classification, only it may be proper to remark that they are kept as much as possible in a systematic form. Thus the manufacture of hats, of which the base is generally a woollen fabric, is given under WOOLLEN MANUFACTURE, and under ORES we give the general processes for preparing the metals employed in different metallurgical works.

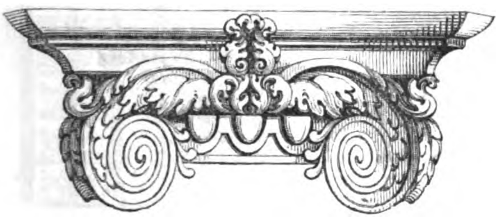
THE

BRITISH CYCLOPÆDIA.

DIVISION I.—ARTS AND SCIENCES.

Abacus, or **Abaciscus**, in *Architecture*. The Greek derivative of this word signifies a table or tablet, which form the ancient abacus invariably assumed. The accompanying wood-cut will point out the situation of the abacus with reference to the capital of a Grecian column, of which this species of architectural ornament formed the upper part.



The shape of the abacus differs in the various orders. In the remains of ancient Egyptian architecture it is, in some instances, nothing more than a plain cube of stone; and in others, two or more such cubes placed one above the other. Among the Greeks and Romans the abacus is the most essential portion of the capital, though in the original column it was only a tile to protect the upper portion of the shaft. In the Tuscan, the Doric, and the Ionic orders of architecture, the plan of the abacus is rectangular; but in the Corinthian, and Roman, or Composite orders, it is hollowed into circular indentations; and, except in a very few instances, as in those of the capitals of the Poikile at Athens, cut off at the angles. The term abacus is also, but inappropriately, applied to the upper member of any large pedestal.

Abacus is also the name of an ancient instrument for facilitating operations in arithmetic. The working of simple numbers by counters, was obviously well fitted for unfolding the principles of calculation, and it is a curious fact, that in our own times, both Bell and Lancaster have found it advisable to resort to instruments closely resembling those employed in the elementary schools of Greece and Rome. The greater part of the instruments used by the ancients were of a very simple character, and fitted but for the most simple processes; but the apparatus of Napier, Pascal, and Babbage, have given an importance to the subject, which can only be appreciated by those acquainted with the detail of their several assertions. To render this intelligible to our readers, we propose commencing with the earliest form of the abacus, and then tracing its most important improvements, until we arrive at that master-piece of mechanical ingenuity, the machine invented by Mr. Babbage.

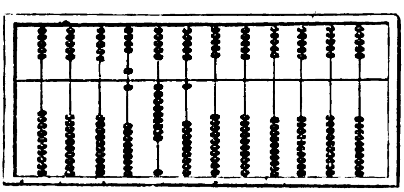
The ancient *abacus* was divided from the right to the left hand, by vertical columns, on which a series of pebbles were placed as counters, to denote units, tens, hundreds, thousands, &c. The labour of counting and arranging those pebbles was afterwards sensibly abridged, by drawing across the board a horizontal line, above which, each single pebble had the power of five. In the progress of luxury, *tali*, or dies made of ivory, were used instead of pebbles, and small silver coins came to supply the place of counters. But the operations with the *abacus* were rendered still more commodious by substituting for such *tali* or counters, small beads strung on parallel threads, and sometimes pegs stuck along grooves. With such an instrument it is not difficult to perceive how the simpler additions and subtractions could be performed with tolerable expedition; but to accomplish a process of multiplication or division, even on the smallest scale, must have been a work of tedious and most irksome labour. Accountants by profession, among the Romans, were styled *calculators* or *rationarii*. Various expedients seem to have been employed for shortening the arithmetical operations. The different positions of the fingers were, for that purpose, used to a certain extent. Boethius treated largely of the subject; and even the venerable Bede, has given very diffuse rules for what was called *digital arithmetic*.

When calculations with counters became more involved, the table on which they were performed, being necessarily of a very considerable size, was called the bench or *bank;* and hence our term for an office where money transactions are negociated. The Court of Exchequer, introduced into England by the Norman Conquest, and intended for auditing the revenue of the crown, had its name from *scaccarium*, which in modern Latin signifies a *chess-board*. The accounts were cast up by the tellers, or *computators*, on a large table covered with black cloth, *chequered* with white lines, on which were placed counters, or small foreign coins, to denote successively pence, shillings, and pounds; proceeding afterwards on the several distinctures of the cloth, by units, tens, hundreds, &c. Sums of money were also rudely marked on *tallies*, so called because they consisted of white sticks of hazel or willow, split up and cut square at both ends; a very fine notch on them denoted a penny, one rather larger a shilling, and one still larger a pound; the notch next in size represented twenty pounds, a larger one expressed a hundred, and the largest of all a thousand. This very strange practice has been handed down to our own times; another striking instance of the blind obstinacy with which

ancient usages, however absurd and ridiculous they may through time have become, are yet retained in public offices, and especially in our courts of law.

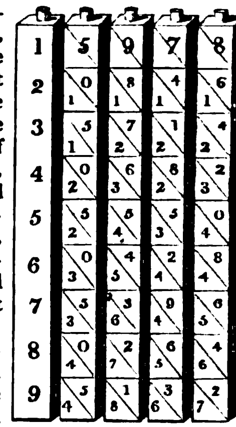
The Chinese have, from the remotest antiquity, used in all their calculations, an instrument which they call *Swan-pwan*, or Swan pan, and which is somewhat similar to the Grecian abacus. There are large and small ones. Those for mercantile purposes consist of many rows of small balls strung on wires, containing fifteen balls on each, with space for their being moved up or down with ease. Those rows of balls are divided by a cross bar of wood, extending from side to side, leaving five balls above and ten below. Each ball of the upper row is of the value of the ten lower balls. By moving one of the upper balls down to the bar, the ten lower balls, which had been moved up to the bar, are at liberty to represent any further sum, till they have all again reached the bar, when another of the upper division is moved down, and so on till the five balls are engaged, when their value is represented by one ball on the adjoining wire, on the left hand, and so on to any amount. For example: the product of the first five balls would give 50, or five tens; and five of the second would give 250, or five fifties; and five of the third would give 1250, or five 250's, and so on to any extent. The person who reckons generally begins about the centre of the board, allowing himself sufficient space towards the left hand. To illustrate the principle by English money, the process is simply thus:—Suppose an article cost £1 7 4 it would be denoted by one ball on one row, seven on the second row, and four on the third; and the second sum to be added 10 1 9. They now begin on the right hand, 9 and 4 being 13, they would move one ball up under the seven balls, and move down three balls from the four, leaving one; by adding one to the eight balls, it would become nine; 10 and 1 making 11, they would move down one from the upper balls, and retain the lower ball, the total would then read £11 9*s.* 1*d.*: as shown in the accompanying cut.

£1	7	4	
10	1	9.	
£11	9	1	



In the divisions of a tale or of a dollar, their highest fraction being nine, and two nines giving 18, the ten being represented by one ball, and the eight differently placed, an error can seldom occur in their mode of addition, or even in subtraction. The swan-pwan is an invariable companion of every counter throughout the whole of China, as it saves the trouble of putting down the prices of a number of articles, and then casting them up, the amount being shown as quick as a person can name them separately.

In performing the ordinary operations of multiplication and division, it is easy to perceive that our object would be much facilitated, if we possessed previously a set of numbers expressing the several products of the multiplicand and each of the nine digits. Such a table might be procured by the simple addition of that multiplicand to itself, the requisite number of times in order to produce its double, triple, quadruple, &c.; but an abridgement of this nature, in the calculation, could only be obtained by an operation much longer than that which it is desired to abridge. The celebrated Napier, the ingenious inventor of logarithms, has, however, contrived an instrument, by means of which this difficulty is removed, and which, by the performance of a very simple mechanical operation, is made at once to present the required product of the multiplicand and any single figure. It is usually known by the name of Napier's Rods or Bones, and is described by the noble inventor in his *Rhabdologia*, published at Edinburgh in 1617.



The accompanying engraving exhibits this instrument, or rather a portion of it, the nature of which may be best imagined by supposing the ordinary multiplication table to be drawn on a plate of metal, ivory, or pasteboard, and conceiving the vertical columns of which it is composed, to be then cut asunder, so as to be rendered moveable. The figures contained in the small squares of that table are, however, differently written on these columns or rods, each of which is divided by a diagonal line into two small triangles, in the one of which is found the unit's digit, and in the other the ten's digit of the number which belongs to that square, the same arrangement being uniformly preserved throughout the whole number of squares. The apparatus will then consist of a number of these rods ranged vertically, each of which is headed by one of the nine digits, beneath which are placed in succession the respective products of that number multiplied by 2, 3, 4, &c., 9. It is obvious that of each of these rods there must be more than one; for as many times as any figure occurs in the multiplicand, so many rods of that species, that is, with that figure at the top of them, must we have. For all ordinary calculations, six of each will be sufficient; and there must also be as many rods of cyphers. To perform the operation of multiplication with this instrument, we must first lay down a rod headed by unity, which may be called the index rod; to the right of this is to be placed another, at the top of which is the figure in the highest place of the multiplicand; adjoining this is to be set a third, headed by the next figure of that number, and so on with each, until as many rods (exclusive of the index) have been laid down as there are digits in the multiplicand. The instrument will then present a table of products of the multiplicand and each of the nine digits; for in the line of squares standing against any figure of the index rod, is the product of the multiplicand and that figure. Therefore, the sum of the products contained in the respective lines of squares which stand opposite to each figure of the index rod, corresponding to the figures of the multiplier, is the result required in an operation of multiplication.

It should be observed, however, that the figures in those squares must be reduced to the ordinary rotation, before they can be so transferred for addition, as

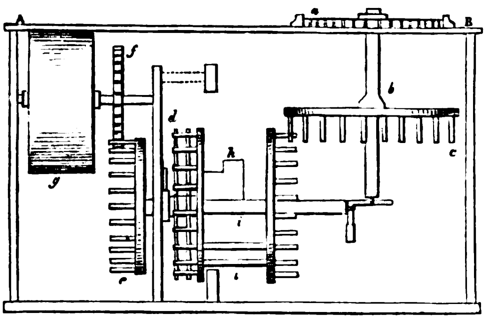
will be seen in the following example:—to multiply 5,978 by 937. Having placed the rods in the proper situation for 5,978, as in the above figure, we must proceed to add together the numbers contained in the line of squares opposite to the figure in the index rod, which corresponds to the first figure of the multiplier, namely, 7. A simple inspection of the illustration will show that the figures contained in the two contiguous triangles of each two squares are of the same denomination, thereby greatly facilitating the addition of the numbers contained in any line of squares. The sum of the products contained in the line opposite 7 is 41,846; the result for the next figure of the multiplier 3, is 17,934 tens; and for 9, 53,802 hundreds; the sum of these three numbers is 5,601,386, the result required. The application of the instrument to the purposes of division will be evident upon a moment's reflection.

One great and obvious defect of an instrument of the above nature is, that its performance is imperfect, inasmuch as the sum of the products contained in any line of squares is not completely arranged; the mental operation of adding together the digits of the same denomination being requisite in order to obtain a result conformable to the ordinary system of notation. To obviate this defect, several machines have been invented by various individuals so constructed as to collect together all the digits of the same denomination, and, as it were, register the excess of any above 9. The great Pascal was the first who succeeded in reducing to pure mechanism the performance of a variety of arithmetical operations, and a description of the instrument by which he effected this object is to be found in the fourth volume of the *Machines Approuveés* of M. Gallon. In 1673, Sir Samuel Morland published an account of two different machines which he had invented, one for the performance of addition and subtraction, and the other for that of multiplication, without however developing their internal construction. About the same period the celebrated Leibnitz, the marquis Poleni, and M. Leupold, directed their attention to the subject, and invented instruments for accomplishing the same purpose by different methods. Leibnitz published his plan in the *Miscellanea Berolensia* of the year 1709, giving, however, only the exterior of the machine; and Poleni communicated an account of his to the same work, but also explained its internal construction. Both of these machines, together with that of Leupold, were subsequently described in the *Theatrum Arithmetico-Geometricum* of the latter, published at Leipsic in 1727. We must not omit to mention the *Abaque Rhabdologique* of M. Perrault, inserted in the first volume of the work, which we have referred to above, the *Machines Approuveés*, by the Paris Academy, which contains also an account of a *Machine Arithmétique* of M. Lespine, and of three distinct ones of M. Hillerin de Boistissandeau. In 1735, professor Gersten, of Giessen, communicated to the Royal Society of London, a very detailed description of an instrument of this nature which he had invented, and the hint of which, he says, "I took from that of M. de Leibnitz, which put me upon thinking how the inward structure might be contrived."

To give our readers an idea of the general construction of these machines, and of the principles on which it proceeded, we will select for explanation that of Pascal, the earliest. Of those which have since been contrived, there are some which have been considered to possess advantages over that in practice; but as the first of its kind, and as one which may have served as a model to many of its successors, it is the object of our preference on the present occasion.

The accompanying illustration exhibits a general view of the instrument with the operator at work on it, who has one hand employed in putting into motion one of the moveable wheels of the apparatus, and the other engaged in connecting the operations of the machine with the figures contained on the paper by his side. It consists of a box covered with a plate of metal, pierced on one side with several square holes, as represented in the figure. On the opposite side of the plate are a number of toothed wheels, each moveable, and turning freely about its own centre. The first to the extreme right has 12 teeth; the second, proceeding from right to left has 20, and all the others have 10. About each of these wheels an outer rim or circle is described on the surface of the plate, which circle is divided into the same number of equal parts as there are teeth in the wheel which it surrounds, and which is moveable, as it were within it. The figures corresponding to each of these points of division are inscribed on all the fixed circles, commencing with 0 at that portion of each which is nearest to the extremity of the side of the box on which they are placed, and proceeding round in the direction of from left to right. Passing over at each of these *zero* points of division, and attached to the surface of the plate, is a small tongue of metal which projects slightly over the enclosed wheel, so as not however to rest on or be in contact with it, but simply for the purpose of arresting the progress of the rod held in the hand of the operator, as seen in the above illustration, when engaged in imparting motion to any one of the wheels. From the number of teeth which we have given to those wheels, it is evident that the one to the extreme right, which contains 12, is intended for what may be termed a pence wheel; the second, which has 20, for a shillings wheel; the third, which has 10, for the units of pounds; the fourth, for tens; the fifth, for hundreds; the sixth, for thousands; the seventh, for tens of thousands; and the eighth, for hundreds of thousands. By enlarging the machine, this number might be increased, and the power of the instrument extended.

We may now proceed to point out the internal arrangement of the machinery. Motion is communicated by the wheel and axis *a b*, which is furnished with a contrite wheel *c*. This actuates the next in the series which is placed in the opposite direction. On the same axis are placed two similar wheels *d e*, the last of which gives motion to the wheel and barrel *f g*. There are two apertures in the upper plate A B, through which the figures on the barrel may be seen, so that the person who moves the wheel *a* may readily register the amount of motion, by observing the figures as they pass these apertures.



In the complete machine there are several of these trains of wheels, and they communicate with each other by a small lever *h*, shewn in the diagram. Now, if we suppose the first of these barrels to have made an entire revolution, the two connecting bars *i i*, will have raised the lever and moved the communicating wheel of the next train one tooth forward in its course. If, for example, it be the barrel which represents shillings, it will by this means indicate a single pound on the divided circle of the next train.

Notwithstanding the skill and contrivance bestowed upon instruments of a nature similar to that we have just described, their power is necessarily but very limited, and they bear no comparison either in ingenuity or magnitude to the grand design conceived, and nearly executed, by Mr. Babbage. Their very highest functions were but to perform the operations of common arithmetic; Mr. Babbage's engine, it is true, can perform these operations, it can also extract the roots of numbers, and approximate to the roots of equations, and even to their impossible roots; but this is not its object. Its function in contradistinction to that of all other contrivances for calculating, is to embody in machinery the method of differences, which has never before been done; and the effects which it is capable of producing, and the works which, in the course of a few years, we expect to see it execute, will place it at an infinite distance from all other efforts of mechanical genius. Great as the power of mechanism is known to be, yet we venture to say, that many of the most intelligent of our readers will scarcely admit it to be possible, that astronomical and navigation tables can be accurately computed by machinery; that the machine can itself correct the errors which it may commit; and that the results, when absolutely free from error, can be printed off without the aid of human hands, or the operation of human intelligence. "All this, however," says Sir David Brewster, in his entertaining *Letters on Natural Magic*, "Mr. Babbage's machine can do; and, as I have had the advantage of seeing it actually calculate, and of studying its construction with Mr. Babbage himself, I am able to make this statement on personal observation." It consists essentially of two parts, a calculating, and a printing part, both of which are necessary to the fulfilment of the inventor's views, for the whole advantage would be lost if the computations made by the machine were copied by human hands and transferred to types by the common process. The greater part of the calculating machinery, of which the drawings alone cover upwards of 400 square feet of surface, is already constructed, and exhibits workmanship of such extraordinary skill and beauty, that nothing approaching to it has hitherto been witnessed. In the printing part, less progress has been made in the actual execution, in consequence of the difficulty of its contrivance, not for transferring the computations from the calculating part to the copper, or other plate destined to receive them, but for giving to the plate itself that number and variety of movements which the forms adopted in printed tables may call for in practice.

The practical object of the calculating engine is to compute and print a great variety and extent of astronomical and navigation tables, which could not otherwise be done without enormous intellectual and manual labour, and which, even if executed by such labour, could not be calculated with the requisite accuracy. Mathematicians, astronomers, and navigators do not require to be informed of the real value of such tables; but it may be proper to state, for the information of others, that *seventeen* large folio volumes of logarithmic tables alone were calculated under the superintendance of M. Prony, at an enormous expense to the French government; and that the British government regarded these tables to be of such national value, that they proposed to the French Board of Longitude, to print an *abridgement* of them at the joint expense of the two nations, and offered to advance £5000 for that purpose. But, besides logarithmic tables, Mr. Babbage's machine will calculate tables of the powers and products of numbers, and all astronomical tables for determining the positions of the sun, moon, and planets; and the same mechanical principles have enabled him to integrate innumerable equations of finite differences, that is, when the equation of differences is given, he can, by setting an engine, produce at the end of a given time, any distant term which may be required, or any succession of terms commencing at a distant point.

On the means of accomplishing this, we need make no apology for quoting Mr. Babbage's own words. "As the possibility of performing arithmetical calculations by machinery may appear to non-mathematical readers too large a postulate, and as it is connected with the subject of the division of labour, I shall here endeavour, in a few lines, to give some slight perception of the manner in which this can be done; and thus to remove a small portion of the veil which covers that apparent mystery. That nearly all tables of numbers which follow any law, however complicated, may be formed, to a greater or less extent, solely by the proper arrangement of the successive addition and subtraction of numbers befitting each table, is a general principle which can be demonstrated to those only who are well acquainted with mathematics; but the mind, even of the reader who is but very slightly acquainted with that science, will readily conceive that it is not impossible, by attending to the following example. Let us consider the subjoined table. This table is the beginning of one in

very extensive use, which has been printed and reprinted very frequently in many countries, and is called a table of square numbers.

Terms of the Table.	A. Table of squares.	B. First Difference.	C. Second Difference.
1	1		
		3	2
2	4		
		5	
3	9		2
		7	
4	16		2
		9	
5	25		2
		11	
6	36		2
		13	
7	49		

Any number in the table, column A, may be obtained by multiplying the number which expresses the distance of that term from the commencement of the table by itself; thus 25 is the fifth term from the beginning of the table, and 5 multiplied by itself, or by 5, is equal to 25. Let us now subtract each term of this table from the next succeeding term, and place the results in another column (B), which may be called first-difference column. If we again subtract each term of this first-difference from the succeeding term, we find the result is always the number 2 (column C); and that the same number will always recur in that column, which may be called the second-difference, will appear to any person who takes the trouble to carry on the table a few terms further. Now, when once this is admitted as a known fact, it is quite clear that, provided the first term (1) of the table, the first term (3) of the first-differences, and the first term (2) of the second or constant difference are originally given, we can continue the table to any extent, merely by simple addition: for the series of first-differences may be formed by repeatedly adding the constant difference 2 to (3) the first number in column B, and we then necessarily have the series of odd numbers, 3, 5, 7, &c.; and again, by successively adding each of these to the first number (1) of the table, we produce the square numbers."

Having thus thrown some light on the theoretical part of the question, Mr. Babbage proceeds to shew that the mechanical execution of such an engine as would produce this series of numbers, is not so far removed from that of ordinary machinery as might be conceived. He imagines three clocks to be placed on a table, side by side, each having only one hand, and a thousand divisions instead of twelve hours marked on the face; and every time a string is pulled, each strikes on a bell the numbers of the divisions to which the hand points. Let it be supposed that two of the clocks, for the sake of distinction called B and C, have some mechanism by which the clock C advances the hand of the clock B one division for each stroke it makes on its own bell; and let the clock B by a similar contrivance advance the hand of the clock A one division for each stroke it makes on its own bell. Having set the hand of the clock A to the division I, that of B to III, and that of C to II, pull the string of clock A, which will strike one; pull that of clock B, which will strike three, and at the same time, in consequence of the mechanism we have referred to above, will advance the hand of A three divisions. Pull the string of C, which will strike two and advance the hand of B two divisions, or to division V. Let this operation be repeated; A will then strike four; B will strike five, and in so doing will advance the hand of A five divisions; and C will again strike two, at the same time advancing the hand of B two divisions. Again pull A, and it will strike nine; B will strike seven, and C two. If now those divisions struck, or pointed at by the clock A be attended to and written down, it will be found that they produce a series of the squares of the natural numbers; and this will be the more evident, if the operation be continued further than we have carried it. Such a series could of course be extended by this mechanism only so far as the three first figures; but this may be sufficient to give some idea of the construction, and was in fact, Mr. Babbage states, the point to which the first model of his calculating engine was directed.

In order to convey some idea of the power of this stupendous machine, we may mention the effects produced by a small trial engine constructed by the inventor, and by which he computed the following table from the formula $x^2 + x + 41$. The figures as they were calculated by the machine, were not exhibited to the eye as in sliding-rules and similar instruments, but were actually presented to it on two opposite sides of the machine, the number 383, for example, appearing in figures before the person employed in copying. The following table was calculated by the engine referred to:

41	131	383	797	1373
43	151	421	853	1447
47	173	461	911	1523
53	197	583	971	1601
61	223	547	1033	1681
71	251	593	1097	1763
83	281	641	1163	1847
97	313	691	1231	1933
113	347	743	1301	2021

While the machine was occupied in calculating this table, a friend of the inventor undertook to write down the numbers as they appeared. In consequence of the copyist writing quickly, he rather more than kept pace with the engine at first, but as soon as five figures appeared, the machine was at least equal in speed to the writer. At another trial, thirty-two numbers of the same table were calculated in the space of two minutes and thirty seconds, and as these contained eighty-two figures, the engine produced thirty-three figures every minute, or more than one figure in every two seconds. On a subsequent occasion, it produced 44 figures per minute; and this rate of computation could be maintained for any length of time.

It may be proper to add, that M.. Babbage stated to the editor of this work, that he considered the powers of his machine as scarcely at all developed—indeed, that the automaton was yet but in its infancy. If such be the childhood of this gigantic engine, what may we not expect from its maturity? There is a general belief that this gentleman has received a large parliamentary grant as a reward for his invention; this is, however, a vulgar error. He has superintended the construction of the instrument at the expense of the Government, but he has not directly or

indirectly received the slightest pecuniary compensation for his services.

Abaissed, *abaissé*, a term used in Heraldry to express the situation of the *fesse*, or any other bearing, when it is depressed below the centre of the shield.

Abas, a weight which is used in Persia for weighing pearls. According to Dr. Kelly's late work on Oriental Metrology, it answers to 3.66 diamond grains English, or 2.25 troy grains = .148 decigramme.

Abassi, or Albaajer, a silver coin current in Persia, equivalent in value to two mamoodis, or four chayés. It took its name from Schah Abbas II., king of Persia, under whom it was struck, and is worth about one shilling of our money.

Abatement, a term used in Heraldry, to denote a mark annexed to the paternal coat, in order to express or point out some ungentlemanlike behaviour or infamy, by which that coat is abated or lowered in dignity. The marks of abatement mentioned by heraldic authors are nine in number; but although anciently heralds, or officers of arms, might have settled these bearings as the proper *tesseræ* or abatement of honour to deter men from the commission of such dishonourable acts, scarcely an instance of any one of them having been actually borne, is given by heraldic writers, and the French discard it altogether as an English fancy.

Abatis, a species of military defence formed of trees cut down and laid with their branches turned towards the enemy, so as to protect troops stationed behind them. They are sometimes placed before redoubts and other works, to render attacks difficult; and along the skirts of a wood, in order to prevent the enemy from getting possession of it. In this case, the trunks serve as a breast-work, behind which the troops are posted, and should therefore be so disposed, that the parts may, if possible, flank one another. In addition to these applications, the abatis may often be of essential service, by retarding the progress of the enemy.

Abb, the yarn of a weaver's warp, whence the wool of which it is made is termed abb-wool.

Abdomen, or lower venter, the anatomical term for the belly. This cavity is that division of the human body which is situated betwixt the thorax and the pelvis. It is bounded above by the arch of the diaphragm, behind, by the spine, on the sides and fore part, by the abdominal muscles; and below, the abdominal viscera are supported by what are termed the alœ ilii and the pubis. It contains the viscera more or less immediately connected with digestion, and the kidneys which secrete the urine.

To give greater accuracy to the description of the seat of the viscera, or perhaps rather more strictly, to connect the knowledge of the internal parts with the exterior of the belly, it has been long customary to mark certain arbitrary divisions on its surface, which are called regions.

The epigastric region is the upper part of the belly, under the point of the sternum, and in the angle made by the meeting of the cartilages of the ribs with the sternum. Upon the sides, under the cartilages of the ribs, are the hypochondriac regions, or the right and left hypochondrium. These three regions compose the upper division of the abdomen, in which are seated the stomach, liver, spleen, pancreas, duodenum, and part of the arch of the colon. The space surrounding the umbilicus between the epigastrium and a line drawn from the crest of one os ilii to the other, is the umbilical region. The hypogastric region is of course the lowest part of the belly, consisting of the angle between the umbilical region, the spines of the ossa ilii, and the pubis. The two lateral spaces between the false ribs and the spine of the os ilii, are the iliac regions, or the loins.

The boundaries of the abdomen are everywhere lined by a thin and elastic membrane called the peritoneum, which also more or less envelopes the contained viscera. The peritoneum may be compared to a flaccid bladder behind, and on the outside of which the intestines and other supposed contents are placed. This membrane is then folded around them, and the two sides of the bladder, after enfolding the intestines, are brought together, forming the mesentery. The peritoneum is therefore contiguous on its internal surfaces, or only separated by a vapour called halitus, which after death condenses into a watery fluid.

The term viscera, though referring more particularly to the fleshy or solid contents of the great cavities, is applied generally to all the parts contained in them. The economy of the abdominal viscera is very important in the processes of digestion. The organs destined to receive the food, and to perform the first of those changes upon it, which after a due succession of actions fit it for becoming a component part of the living body—are the stomach and intestines, which may be considered as primary, and the glandular viscera, the liver, the pancreas, and in all probability the spleen, as subservient or secondary organs. These may be divided into the membranous or floating viscera, comprising the whole track of the intestinal canal, and the glandular viscera; or, what is still better, they may be distinguished into those parts which have action and motion, and those which are quiescent, or possessed of no power of contraction. Thus the stomach, intestines, gall-bladder, and bladder of urine (though this belongs to the pelvis), have muscular coats, and possess the power of contracting their cavities; while the liver, spleen, pancreas, and kidneys have no muscularity but in their vessels and excretory ducts.

The intestinal canal may be divided into three parts; the stomach, the great and the small intestines. The small intestines are subdivided into the duodenum, jejunum, and ileon; the great, into the cœcum, colon, and rectum. The stomach, into which the food is conveyed by the œsophagus, or gullet, is the seat of the digestive process; in the duodenum, the food receives the addition of the secretions from the liver and pancreas, and is still further adapted to animalization; in the long tract of the jejunum and ileon the nutritious part is absorbed; and in the great intestines the effete matters are carried slowly forward, and at the same time suffer a further absorption of their fluid contents, until as fœces they lodge in the rectum, or last division of the canal. From this view, it is apparent that each of the divisions of the intestinal canal is marked by some peculiarity in its use or function; and for a more detailed account of their structure individually, we must refer to the several portions of which it is composed.

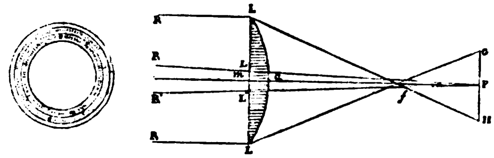
Abductor, a term applied to those muscles which draw backwards the moveable parts into which they are inserted, and of which there are many in the human body.

Aberration of light. We see an object because

the rays of light proceeding from it strike our eyes, and we see the place of the object in the direction in which they proceed. Let us now imagine the earth, in its circuit round the sun, just arrived opposite to a fixed star, which sends off rays perpendicularly to the direction of the earth's motion. The eye of the spectator meets the ray, and as he perceives not his own motion, he supposes the light to be moving in an opposite direction; as, when we sail in a boat, the trees on the shore appear to pass along by us. Thus the eye misses the perpendicular ray, but meets an oblique one, and thence receives the impression of the light in the direction which results from this compound motion, namely, in the diagonal of a parallelogram, the sides of which represent the real motion of the light, and the apparent one (i. e. the motion of the earth), which take place at the same time. The spectator sees the star in its true place only when he is either approaching it, or receding from it, in a straight line. When moving in any other direction, the star appears a little in advance of its true position in the same direction (the maximum is 20″—25″); and we call by the name of *aberration of light* these apparent changes in the situation of the heavenly bodies, occasioned by the motion of the earth. We easily see that these changes are common to all the heavenly bodies, and are only more striking in the case of the fixed stars. They afford an additional proof of the motion of the earth. In consequence of this abberration, the fixed stars appear, during the revolution of the earth about the sun, according as they are situated, either in the plane of the ecliptic, or in its poles, or somewhere between them, in the first case to deviate in a straight line to the right or left of their true place, in the second to describe a circle, in the third an ellipse about that point, which further observation determines to be their real situation. This discovery we owe to Bradley.

The spherical *aberration of lenses* must be understood before the student can at all comprehend the principles of optics. It is generally supposed that the rays refracted from lenses or magnifying glasses meet exactly in a focus; but this is by no means strictly true, as those which pass through the centre or axis of the lense go beyond those which are incident at a greater distance.

In order to understand the cause of spherical aberration, let LL be a plano-convex lens, one of whose surfaces is spherical, and let its plane surface, L *m* L, be turned towards parallel rays R L, R L. Let R′ L′, R′ L′, be rays very near the axis A F of the lens, and let F be their focus after refraction. Let R L, R L be parallel rays incident at the very margin of the lens, and it will be found by the method of projection, that the corresponding refracted rays L *f*, L *f* will meet at a point much nearer the lens than F. In like manner intermediate rays between R L and R′ L′ will have the foci intermediate between *f* and F. Continue the rays L *f*, L *f*, till they meet at G and H, a plane passing through F. The distance *f* F is called the *longitudinal spherical aberration*, and G H the *literal spherical aberration of the lens*. In a plano-convex lens placed like that in the figure, the longitudinal spherical aberration *f* F is no less than 4½ times *m a*, the thickness of the lens. It is obvious that such a lens cannot form a distinct picture of any object in its focus F. If it is exposed to the sun, the central part of the lens L′ *m* L′, whose focus is at F, will form a pretty bright image of the sun at F; but as the rays of the sun, which pass through the outer part of L L of the lens, have their foci at points between *f* and F, the rays will, after arriving at those points, pass on to the plane G H, and occupy a circle whose diameter is G H; hence the image of the sun in the focus F will be a bright disc, surrounded and rendered indistinct by a broad halo of light, growing fainter and fainter from F to G and H. In like manner, every object seen through such a lens, and every image formed by it, will be rendered confused and indistinct by spherical aberration.



The form assumed by the sun's disc is shown by the radial circles at the opposite extremity of the wood-cut.

These results may be illustrated experimentally by taking a ring of black paper and covering up the outer parts of the face L L of the lens. This will diminish the halo G H, and the indistinctness of the image; and if we cover up all the lens excepting a small part in the centre, the image will become perfectly distinct, though less bright, than before, and the focus will be at F. If, on the contrary, we cover up all the central part, and leave only a narrow ring at the circumference of the lens, we shall have a very distinct image of the sun formed about *f*.

For the aberration of light, see the elementary works on astronomy, the dictionaries of natural philosophy by Gehler, Fischer, &c. There is a very good account of it in Biot's *Traité Elémentaire d'Astronomie Physique*, Paris, 1811, 2d Treatise, vol. 3, page 120, et seq. Tables of aberration, accompanied with explanations, are to be found in the baron von Zach's works, *Tabulæ speciales Aberrationis et Nutationis, etc.*, Gotha, 1806, and in the same author's *Nouvelles Tables d'Abérration et de Nutation pour* 1404 *Etoiles, avec une Table générale d'Aberration pour les Planètes et les Comètes*, Marseilles, 1812, and *Supplément*, 1813.

Abluents, medicines applied to wash off from the external or internal surfaces of the body any matters adhering improperly to them.

Abomasum, the fourth stomach of ruminating animals, or that in which the process of digestion is completed.

Abscess, a term applied in Surgery to a cavity containing pus or a collection of puriform matter.

Abscissa. See *Conic Sections*.

Absorbent System, the organs which are employed in the performance of the process of absorption, or that by which the substances that serve for the growth and support of the body are carried into the blood and are assimilated to that fluid. It appears to be a general principle in the animal economy, that all the particles of which the body is composed, after a certain period, lose the power of performing their appropriate functions; and that it consequently becomes necessary to have them replaced by new matter. It is by means of absorption that this exchange of particles take place, the former constituents being taken up by the vessels and returned into the general circulation, to be either discharged, or em-

ployed under some new form, while a different set of absorbents receive the recent matter from the products of digestion, and likewise convey it to the blood, whence it is distributed to all parts of the body. The apparatus by which this process is effected, or the absorbent system, may be regarded as consisting of four parts, the lacteals, the lymphatics, the conglobate glands, and the thoracic duct. It is to Aselli that we are indebted for our acquaintance with the lacteals as a specific and distinct system, possessing a peculiar structure and an appropriate office—a discovery which he made in the year 1622. In the course of his dissections, he observed a series of vessels, unconnected with the arteries and veins, dispersed over the mesentery of a dog; and in consequence of the chyle with which they were filled, he gave them the name of lacteals. After they have acquired a sufficient degree of magnitude, these vessels may be easily recognized along the mesentery; like the venous part of the sanguiferous system, the small branches run together to four larger ones, while these again unite, until the whole compose a few great trunks which terminate in the lower end of the thoracic duct. They are furnished with numerous valves of a semi-lunar form, disposed in pairs, and so as to prevent the retrograde motion of the contents of the vessels. The small branches frequently anastomose with each other, more so, indeed, than either the veins or the arteries; for it is a general law of nature, that the smaller the vessels of every kind, the more freely they communicate and unite with each other. The lacteals are further characterized by the thinness and transparency of their coats, by which they are rendered very difficult of detection, except when they are distended with the white and opaque chyle.

The discovery of the lymphatics was a few years posterior to that of the lacteals; for although their structure and composition are nearly similar, yet, in consequence of their contents being transparent and colourless, they are less easily detected. Like those vessels, they are composed of a fine and transparent, but firm and elastic substance, are provided with numerous valves, and form frequent anastomoses. But though analogous to the lacteals in their principal function and in their ultimate destination, they differ from them in their situation and in their contents; for while those vessels are confined to the mesentery, and serve only to convey the chyle, the lymphatics are found in almost every part of the body, and are filled with a transparent and colourless fluid, which, as its name imports, was supposed to consist principally of water. Their larger channels are arranged into two principal series or systems, one near the surface, and the other more deeply seated. These main branches, for the most part follow the course of the great veins, and are finally reduced to three or four great trunks, terminating in the thoracic duct. This, as we have before observed, receives also the tributary stream of the anastomosing lacteals, and pours the whole of the complicated fluid steadily and slowly, by means of a valve placed for this purpose at its opening, into the left subclavian vein, whence it is conveyed to the heart.

The conglobate, or lymphatic glands, compose a conspicuous portion of the absorbent system. They are met with in different parts of the body, always connected with the lymphatics. They are of various sizes, sometimes simple, sometimes in clusters; and although their use is not understood, we may presume that they fulfil some important purpose from the circumstance of every absorbent vessel during its course passing through one or more of these glands. Although we are not acquainted with the nature of the function which is exercised by these glands, we may fairly presume that they tend in some way or other to the completion or the perfection of the absorbent system, as they are found principally in the higher orders of animals. In those of an inferior description, we have the vessels without the glands, while in those of a still lower order, neither the vessels nor the glands can be detected, so that the process of absorption must be carried on by some more simple apparatus. Respecting the structure of these glands there exists a controversy, whether they contain cells, or whether they consist of a mere congeries of vessels; the earlier anatomists maintaining the former, while the more recent authors adhere to the latter opinion.

The office of the absorbents is literally expressed by their name; it consists in receiving or taking up certain substances, and in transporting them from one part of the body to another. The substances which are thus taken up may be referred to two only, the chyle and the lymph, the former being received by the lacteals, and the latter by the lymphatics. The immediate object of the action of the two sets of vessels is also essentially different, that of the first being to convey a fluid from the part where it is formed, into the blood, in order that it may directly conduce to the nutrition of the body, the latter serving to remove what is useless and noxious, and to dispose of it in such a manner that it may either be applied to some secondary purpose of utility, or be finally discharged from the system. Although there is some uncertainty respecting the anatomical structure of the mouths of the lacteals, and considerable difficulty in explaining the mode in which the chyle enters them, we can have no doubt that they are so dispersed over the surface of the intestines, as to be able to receive the chyle when it is presented to them. By their contractile power, assisted by the mechanical action of the valves, and probably by other causes, the fluid, when it has once entered the vessels, is necessarily propelled from their extremities towards their trunks, until at length it arrives at the thoracic duct. The action and functions of the lymphatics do not appear to be essentially different from those of the lacteals; but there is one circumstance in which these two sets of vessels seem to differ, that while the latter appear to be capable of receiving nothing but chyle, which they are in some way or other enabled to select from the heterogeneous mass of matter through which it is diffused, the lymphatics, on the contrary, possess the distinguishing property of taking up, as occasion may require, every substance that enters into the composition of the body, as well as extraneous matters of various kinds that are accidently or intentionally placed in contact with their mouths. With respect to the thoracic duct we have no reason to suppose that there is any thing specific in its action, or that, except in size, it differs from the other absorbent vessels. Its particular office appears to be that of serving as a reservoir in which the chyle may be deposited for the purpose of being gradually transmitted into the sanguiferous system, as there is some reason to suspect that injury would ensue if too large

a quantity of this fluid were poured into the veins at any one time.

From the above remarks it appears that we are in little doubt respecting the use of the vascular part of the absorbent system; but this is not the case with its glandular appendages. It can scarcely indeed appear surprising that we are unable to explain their use, while their structure is still involved in so much obscurity, and yet, on the other hand, it may be said that we know so little of glandular action, or of the change which it produces upon the fluids that are subjected to it, that we should rather attempt to elucidate the subject by physiological than by anatomical investigations. The most probable opinions that have been entertained upon the point are, either that these glands are proper secreting organs, and are intended to prepare a peculiar substance, which is mixed with the chyle and lymph, or that they offer a mechanical obstruction to the progress of these bodies, by which means their elements are allowed to act upon each other, and thus to produce some necessary change in the nature of the fluids which pass through them.

From the period of the complete discovery of the lacteals and lymphatics, it has been a general opinion both with anatomists and physiologists, that their appropriate office was absorption; but it has been a very warmly contested point whether this operation was exclusively performed by those organs. The ancients supposed the process of absorption as well as that of secretion, to be effected, not by a distinct set of vessels expressly formed for that purpose, but by the peculiar construction of the arteries, or of the veins, or of both. This hypothesis of the absorption of veins without the interference of lymphatics, has been revived within the last twenty years by M. Majendie and M. Flandrin, of Paris; by these gentlemen experiments have been adduced which bear the marks of great ingenuity in their contrivance, and accuracy in their execution, and the results of which are, perhaps, at least as decisive in favour of venous absorption as had been those of Hewson, the Hunters, and Monro, in support of the opposite doctrine. The positions attempted to be established by M. Majendie are first, that it is certain that the chyliferous vessels (lacteals) absorb chyle; secondly, that it is doubtful whether they absorb any thing else; and, thirdly, that it is not proved that the lymphatic vessels possess the power of absorption; and it is proved that the veins have this power. However little we may feel disposed to assent to this doctrine of absorption merely upon the faith of experiments, at least until they have been further repeated and diversified, we may, in the mean time, go so far as to assert that venous absorption is neither impossible, nor perhaps improbable; and that with the evidence which we now have in its favour, we can admit of no physiological hypothesis, or train of reasoning which necessarily involves its non-existence.

We have before observed, that the only substance which the lacteals appear destined to receive, is the chyle, which is conveyed by them from the intestines, where it is produced, to the thoracic duct; but we have reason to suppose that the contents of the lymphatics are of a more miscellaneous nature. How far they may serve for the purposes of nutrition, it is not, perhaps, very easy to ascertain; but we may venture to assert that nutrition is not their sole, or even their primary, function, that being rather the appropriate office of the chyle. We are indebted to John Hunter for the first consistent hypothesis upon this subject; he conceived that the primary use of the lymphatics was to form and fashion the body so as to give it its proper shape, and to enable it to increase in bulk, while its individual parts retained their appropriate figure and proportionate size. Thus we observe the bone of a young animal to possess a characteristic shape, to have a certain number of projections and depressions in the different parts. If we examine the same bone in the adult animal, we shall find a general correspondence between the parts of both; we have, for the most part, the same number of projections, and bearing the same relation to each other. But it is obvious that this change of shape could not have been effected by the accretion of new matter to the original bone, nor by the distention of the parts already existing; in short, the only way in which it could have been accomplished, is by the removal of the particles of which the young bone was formed, and the gradual deposition of others in their proper situations. An operation of this kind can be effected by no means with which we are acquainted, except absorption; thence we conclude, that the lymphatics alone, or at least in conjunction with the veins, are the agents employed for this purpose. The action of the absorbents is still more strikingly displayed in many morbid states of the system where the effects are more visible to the eye, in the occurrence, in an unnatural situation of an effusion of a fluid or a deposition of a solid, in which cases these extraneous substances are gradually removed.

The mode in which the absorbents act is a point of great uncertainty; with respect to the lacteals, they are said to be furnished with a peculiar apparatus attached to their mouths, called villi, consisting of a number of small vessels that are so disposed as to be brought into direct contact with the fluid intended to enter them, as is supposed, upon the principle of capillary attraction, or of an elective attraction between the mouths of the vessels and the chyle. The lymphatics are capable of absorbing a variety of substances differing most widely in their nature, and a peculiar difficulty attends this part of the subject, arising from the circumstance of the densest solids, being so acted upon, as well as the more fluid components of the body. If solution of the substances be necessary, we are at a loss for a proper solvent; and, on the other hand, it is not easy to conceive how they can else be absorbed. This difficulty is partly explained by some physiologists, who bring forward the operation of the vital principle, and say that as long as a part possesses that principle, it is enabled to resist the action of the absorbents, but that it immediately becomes subject to their influence, when it loses that agent. That part of the process which is the most difficult to comprehend, is not, however, developed,—the nature of the change which converts the materials into that state which adapts them for being taken up by the absorbents.

M. Majendie has originated a new hypothesis respecting the mode in which the organs act; he conceives it to be that of capillary action exercised by the sides of the vessels upon the substances to which they are exposed. It is evident, however, that nothing can enter the vessels by this kind of filtration, except what is perfectly dissolved in the fluids, and he does not inform us how this solution is effected. The

conclusions of this distinguished physiologist have been more lately enforced by a series of elaborate and ingenious experiments, excuted by M. Fodera, from which he deduces the following conclusions: 1. That exhalation and absorption may be referred to transudation and imbibition through the pores of the membranous textures, "capillarité des tissus," which enter into the composition of the organs. 2. That this double effect may be produced in all parts of the body, and that the fluids which are imbibed may be conveyed equally by the lymphatics, or by the arteries and veins. The nature of the experiments, however, implying as they do so great a degree of correctness in the execution, ought to render us extremely cautious in receiving them as conclusive of the results which are attempted to be established from them.

A series of experiments have been performed by Dr. Barry, from which he infers, that absorption depends altogether upon atmospherical pressure. A dose of poison, under ordinary circumstances proving fatal in a few seconds, being introduced into a wound, was rendered completely harmless by the application of an exhausted cupping glass over it; and even when the symptoms had commenced, still the vacuum had the effect of speedily and entirely removing them. We may observe, however, that the poison was not simply laid on the surface, but was inserted into a wound; hence it would be immediately mixed with the blood, and carried by the veins to the central parts of the system.

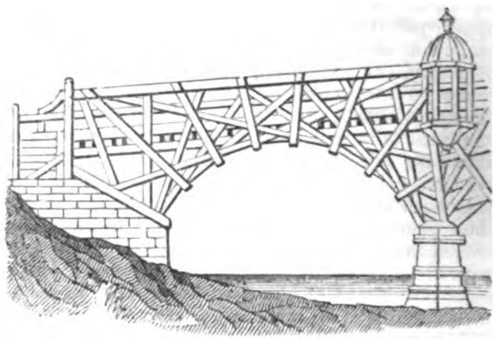
Besides this absorption of substances applied to the skin, and forced into the mouths of the vessels by friction, or other mechanical means, it is supposed, that when the body is immersed in water, the cuticle still remaining entire, the same kind of absorption takes place, and even that the skin has the power of imbibing water from the atmosphere if it exist there in unusual quantity. M. Majendie thinks that the cuticle does not possess this power while in a sound state, either by veins or lymphatics, but that if absaided or strongly urged by the pressure of minute substances that enter into its perspirable pores, the mouths of its minute veins are thus rendered absorbent. The experiments of Dr. Edwards, however, seem conclusive on this point, and would lead us to infer that the function of absorption is actually carried on to a considerable extent, and probably without interruption, although, in differerent degrees, according to the condition of the animal, and the circumstances to which the body is exposed.

Abutment. This architectural term, though very general in its signification, is usually understood to apply but to the extremities of an arch or bridge. Butments of arches are the same with buttresses, and they answer to what the Romans called *sublices*.

One of the most beautiful applications of the abutment will be found in the curved support of the early ecclesiastical and other edifices.

Any person accustomed to the heavy masses of stone and brick work usually employed to resist the lateral pressure in modern edifices, must at once see the advantages of the *flying buttress*, or abutment. About one-third of the materials used in this form possesses a greater degree of strength than could be obtained if the mass had been solid; and then on the score of picturesque effect, the early architect had decidedly the advantage.

The abutments of a bridge, when formed artificially, usually consist of solid masses of masonry, formed by the aid of coffer-dams, or water-tight boxes, in which the abutment is erected; though there are cases in which the abutment is formed naturally.



In the above wood-cut, representing a portion of the wooden bridge erected over the Thames at Walton, by Mr. Ethridge, we have the gravelly soil of the river acting in unison with courses of masonry which form the abutment. The pier in the river acts by forming a direct support, while the abutment combines the perpendicular pressure with the lateral thrust. It will be obvious that the chain bridge, constructed on suspension principles, forms an exception to this view of the abutment; as in the latter case the chains are attached, but have not the same species of pressure.

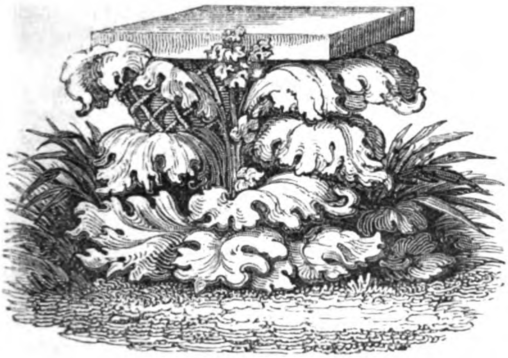
Abyss, in *Heraldry*, the centre of an escutcheon.

Acæna, a Grecian land measure of ten feet.

Acanthus, in *Architecture*, an ornament representing the leaves of the herb bear's breech, which are large and shaggy. It was at first used by the ancients as an ornament to friezes and cornices, and at length to the other members of architecture, but is principally employed as the grand ornament of the *Corinthian and Composite capitals* (See those articles). The Greeks used, for this purpose, the leaves of the cultivated acanthus *(acanthus mollis)*, commonly called brank ursine, or bear's breech, from its shagginess, which grew spontaneously both in Greece and Italy. The Gothic architects and sculptors, on the contrary, have used the wild and prickly acanthus *(acanthus spinosa)*, being smaller in its parts, and more suited to the littleness of their styles of art. Although architecture has made the greatest use of the acanthus, yet the other arts have also adopted it as a chaste and splendid decoration. We find among the ancients, as well as among the moderns, various instruments, household furniture, and utensils, ornamented with leaves of the acanthus. These artists, in preserving the general form and character of the plant, have made their sinuosities and curves more or less prominent to suit their purposes, and have thus given them a more sculpturesque effect. In the Corinthian capital they are executed with more fidelity and elegance; the whole plant surrounds with its aspiring leaves the vase or bell of the capital, as if attempting to lift up the abacus that covers the whole, they then turn down and form themselves into graceful volutes.

The wood-cut on the next page represents the leaves of the plant gracefully bending in the form already described, and the artist has given all that beauty of form which, under accidental circumstances, is said

to have operated on Callimachus in originating the Corinthian capital.



Acatharsia, an impurity of the blood.

Acceleration. See *Motion*.

Accent, a term used in *Music* to denote a certain enforcement of particular sounds, whether by the voice or by instruments. It is generally used at the beginning of bars.

Accident, in *Heraldry*, is an additional note or mark in a coat of arms, not necessarily belonging to it, but capable of being either omitted or retained, without altering the essence of the armour; such as abatement, difference, and tincture. Although often mentioned by heraldic writers, accidents seem to have no particular meaning in blazonry, generally applying to strictures and marks of difference in coat armour.

Accidental, in *Philosophy*, is a term applied to that effect which results from a cause occurring by accident, without apparently following any general laws. Accidental colours are those which seem to depend on the affections of the eye in contradistinction to such as belong to light itself. If we look intensely with one eye upon any coloured spot, such as a wafer placed on a sheet of paper, and immediately afterwards turn the same eye to another part of the paper, we shall see a similar spot, but of a different colour. Thus, if the wafer be red, the seeming spot will be green; if black, it will be changed into white; and in the same manner every colour has a corresponding one into which it is transformed.

Accolé, a French heraldic term which English heralds express by *gorged*, and *collared*. The same word is likewise used by the French to denote two batons, swords, &c. placed behind a shield.

Accompaniment, in *Music* (French, *accompagnement*; Italian, *accompagnamento*), is that part of music which serves for the support of the principal melody (solo or obligato part). This can be executed either by many instruments, by a few, or even by a single one. We have, therefore, pieces of music with an accompaniment for several, or only for a single instrument. The principles on which the effect of the accompaniment rests are so little settled, that its composition is perhaps more difficult than even that of the melody, or principal part. Frequently, the same musical thought, according to the character of the accompaniment, produces a good or bad effect, without our being able to give a satisfactory reason for the difference. Hitherto, the Italians have been most distinguished for expressive accompaniments contained in a few notes, but productive of great effect. In this respect, the Italian music generally surpasses the German and French, as it never weakens the effect of the principal part by means of the accompaniment. The French are far behind both the other nations, in respect to this part of composition, as they frequently estimate the effect by the quantity of notes. The accompaniment requires of the performer the most scrupulous study, and of the composer the greatest care and delicacy. The accompaniment of various solo instruments, as the violin, flute, piano, &c. is extremely difficult, and to give it full effect requires great knowledge and skill. The Italian composers accordingly consider a piano accompaniment for a full orchestra, especially in the recitativo, as a great problem, which they have laboured zealously to solve. As the object of every musical accompaniment is to give effect to the principal part, the accompanier should always aim to support, and by no means to overpower and oppress it. Of all composers, Mozart, even in respect to the accompaniments, claims the first place for the simplicity and beauty with which he amalgamates the leading and accompanying parts, through his unrivalled knowledge and excellent management of the parts for every individual instrument.

Accord, in *Painting*, denotes the harmony that reigns among the lights and shades of a picture.

Accord, in *Music*, see *Concord*.

Accordion. A new musical instrument under this title has lately been imported from Germany, and many of them since constructed in this country. They consist of a double series of vibrating tongues, put in motion by a current of air from a pair of moveable bellows, and when well made, they produce an effect but little inferior to an organ.

Accroché, a term used by French heralds to express one heraldic charge, or bearing, hooked into another.

Acetabulum, in ancient *Metrology*, a Roman measure equal to about one-eighth of our pint, and applicable to both liquid and dry substances. According to Du Pinet, it varied, being for oil, two ounces and two scruples; for wine, two ounces, two drachms, and 1½ grains; and for honey, three ounces, three drachms, one scruple, and two siliquæ.

Acetabulum, in *Anatomy*, is a large spherical cavity in a bone, which receives the convex head of another, thereby forming that species of articulation technically termed enarthrosis. This word is also sometimes used synonimously with cotyledon, to signify a sort of glandular substance found in the placenta of some animals.

Acetic Acid. See *Acid*.

Acetous, an epithet applied to such substances as are sour, or partake of the nature of vinegar.

Acherset, an ancient measure of corn, supposed to be the same with our quarter.

Achiotte, or Achiote, a foreign drug, used in dyeing and in the preparation of chocolate. It is the same with the substance more usually known by the name of *Arnotto*, which see.

Achromatic, or colourless. This word was first introduced by M. La Lande in his work on Astronomy. It is now used to describe those compound optical instruments which transmit light without reducing it into its original elements. The subject will be fully treated of under Optics.

Achteling, a measure for liquids, used in Germany. Thirty-two achtelings make a heemer; four sciltims make an achteling.

ACIDS, in *Chemistry*, a class of substances which are more or less distinguishable by the following properties:—1. When applied to the tongue, they excite that sensation which is called *acid* or *sour*.—2. They change the blue colours of vegetables to a red. The vegetable blues usually employed as a test for this purpose are tincture of litmus and infusion of the red cabbage. If these colours have previously been converted to a green by alkalies, the acids restore them.—3. They readily unite with water.—4. They combine with all the alkalies, and most of the metallic oxides and earths, and form with them various chemical compounds. It may be proper to add, that every acid does not possess all these properties, but as a body, they have those general distinctive characters.

To enable our readers to acquire a clear, and yet perspicuous view of this important class of chemical bodies, it may be adviseable, in the first instance, to briefly enumerate them, and then point out the process used in the manufacture of those chiefly employed in the useful arts. Those of our readers who are disposed to extend their inquiries into the chemical combinations of the acids with other bodies, may do so by referring to the alphabetical arrangement of the work under the several heads of each article. The acids may be thus enumerated:—

Acetic	Hydro-cyanic	Phosphorous
Arsenic	Hydro-fluoric	Prussic
Arsenious	Hydro-sulphuric	Pyro-tartarous
Benzoic	Hypo-phosphorous	Saccholactic
Boletic		Selenic
Boracic	Kinic	Sorbic
Camphoric	Laccic	Stabic
Carbonic	Lactic	Stibious
Cetic	Lampic	Suberic
Chloriodic	Malic	Succinic
Chloro-carbonic	Margaretic	Of Sugar
Chloro-cyanic	Millitic	Sulpho-cyanic
Chromic	Moroxylic	Sulphuretted-chyazic
Citric	Muriatic	
Columbic	Oleic	Sulphuric
Dephlogisticated-muriatic	Oxalic	Sulphurous
	Oxychlolic	Tartaric
Fluo-silicic	Oxymuriatic	Tungstic
Fluoric	Oxyodic	Avric
Formic	Perchloric	Zumic
Gallic	Phosphoric	

We may commence with *sulphuric acid*, being the one most used for chemical and manufacturing purposes.

When sulphur is burned in dry oxygen gas, or vital air, there is no increase in volume; but at common temperatures, a colourless transparent gas is formed, which is distinguished from all other elastic fluids, by a suffocating pungent odour, well known as the smell of burning brimstone. It may be obtained by the action of sulphuric acid upon mercury, in a state of great purity. The mixture may be put into a retort and heated, but the gas must be received over mercury.

It is called sulphurous acid gas.

It extinguishes all burning bodies, when immersed in it, and cannot itself be burned. It is instantly fatal to animal life. When compressed, it assumes the liquid form; or at the degree of cold produced by a mixture of snow, or pounded ice, and salt.

It first reddens blue vegetable colours, and then destroys them; and its bleaching powers are very considerable. The vapours of burning sulphur are much used in whitening silk and straw-work.

One hundred cubic inches of sulphurous acid weigh 67.5: which is exactly double the weight of an equal quantity of oxygen; so that the weights of sulphur and oxygen, in the compound, are equal.

Water at 60° dissolves about 33 times its bulk of sulphurous acid; and the solution possesses its peculiar odour and taste, which is astringent. It cannot, however, be preserved any length of time without change.

A mixture of sulphurous acid and oxygen gas may be kept for any length of time without showing any further disposition to combine, provided they are quite dry. If water be present, the sulphurous acid will gradually unite, with a further proportion of oxygen, and the compound, which is sulphuric acid, will be taken up by the water.

Sulphuric acid is an article of great importance, and is largely consumed in many manufactures; and there are several ways of procuring it for commerce.

By distilling, at a high heat, the salt called green vitriol (which, it will be hereafter seen, is a compound of sulphuric acid and protoxide of iron), a dense, oily, colourless liquid may be obtained; which emits white vapours on exposure to the air. If this liquid be again distilled, at a lower temperature into a receiver surrounded with pounded ice or snow, a transparent, colourless vapour will pass over, which will condense into a white crystalline solid. It is tough and elastic; liquefies at a temperature of 66°, and boils at about 110° or 120°. It has a strong affinity for water, and immediately takes it from the atmosphere. This solid body, there is reason to suppose, is pure *anhydrous* sulphuric acid; but there are some doubts respecting its nature.

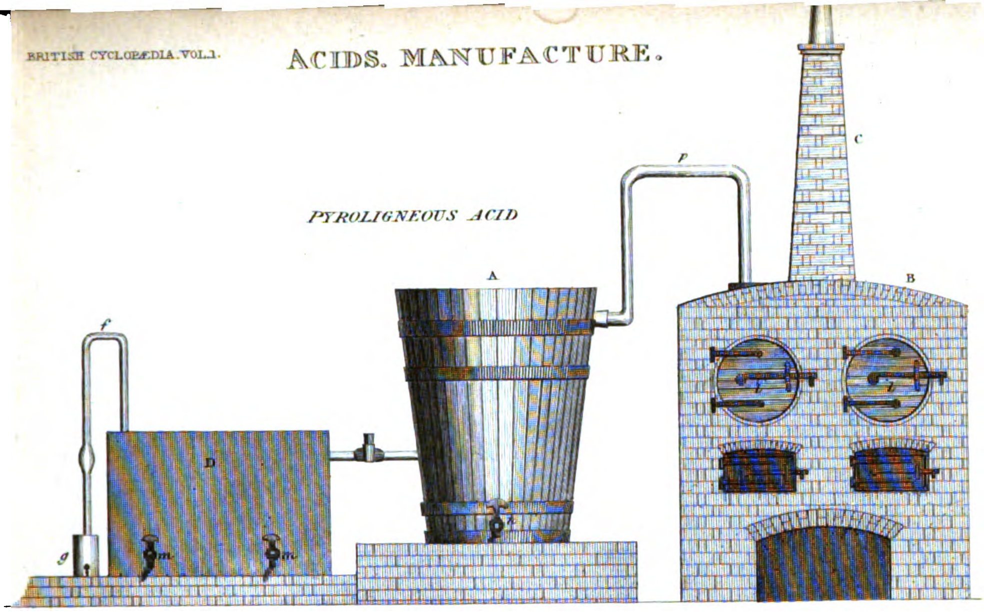
The residue in the retort will be no longer fuming, and is the common oil of vitriol of commerce.

Sulphuric acid is manufactured on the large scale in this country by the combustion of sulphur, which, as we have already seen, converts it into sulphurous acid gas. This gas passes into large leaden chambers, the bottom of which is covered with about six inches of water; together with the sulphurous acid gas, a quantity of the vapour of nitrous acid passes into the leaden chamber. These two acids have the property of uniting together; and they form minute crystals, which fall into the water at the bottom of the chamber. The moment they come in contact, a decomposition takes place; the sulphurous acid is converted into sulphuric acid, and the nitrous acid into deutoxide of azote. This last substance makes its escape in the gaseous state; but immediately comes in contact with the common air of the chamber, and is converted into nitrous acid, which, uniting with a new dose of sulphurous acid, falls again into the water. These decompositions and new formations continually go on as long as the air of the chamber contains oxygen gas and sulphuric acid. The water, when sufficiently impregnated with sulphuric acid, is drawn off from the bottom of the chamber, and concentrated as far as possible in leaden boilers. It is then put into glass or platinum retorts, and kept in a heat of at least 600°, till as much concentrated as possible.

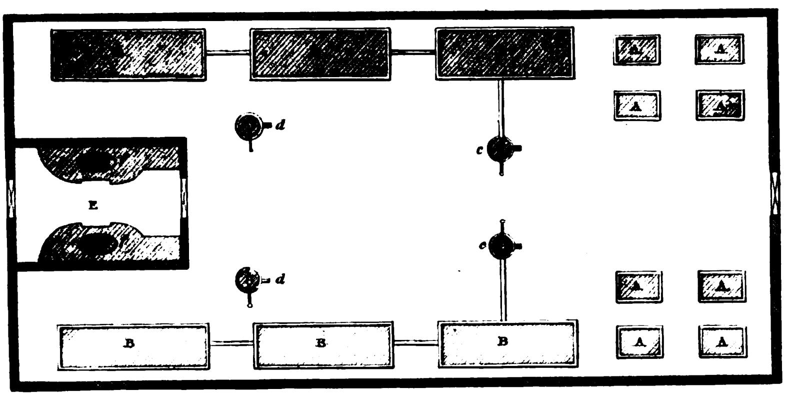
A plan of the arrangement of a large sulphuric acid works is shewn in our plate, ACIDS' *Manufacture*, in which B B are the leaden chambers containing water, and through which the gas passes. A A

ACIDS. MANUFACTURE.

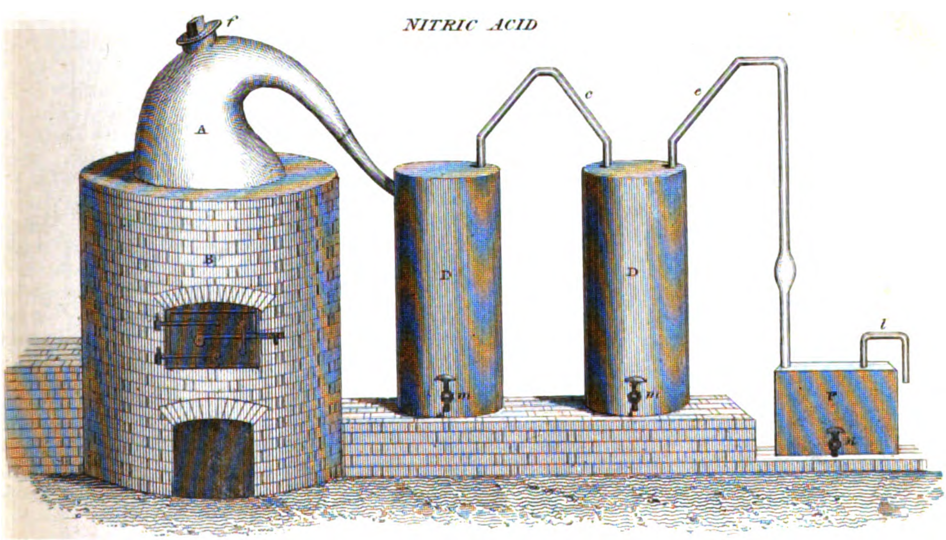
PYROLIGNEOUS ACID



SULPHURIC ACID



NITRIC ACID



London, Published by William Orr, Paternoster Row, Sept.r 29. 1832.

are the boilers of the same material, in which the acid is concentrated prior to its being evaporated in the platinum retorts. The pumps for drawing off the weak acid is shewn at *c c*, *d d*, and the retort room, &c. at E, *f f*.

Acid thus prepared, is a clear, transparent, colourless liquid like water, with a certain degree of consistency, so as to adhere to the sides of a phial like oil. When quite free from all impurity, its specific gravity (when as strong as possible) is 1·847; if it be heavier than this, it is contaminated with lead.

Nitrous Acid.—The next compound in order of practical importance is the nitrous acid, which may be produced by adding oxygen to the deutoxide of nitrogen. The experiment will not succeed over water or mercury, but may be conducted in a glass retort, fitted with a stop-cock, from which the air has been extracted by an exhausting syringe. In this way a mixture may be made of 2 measures of the deutoxide, and 1 measure of oxygen, which will be condensed into half their volume, and form a deep orange-coloured gas: 2 volumes of the deutoxide are composed, as we have seen,

1 volume of nitrogen, and
1 volume of oxygen,

and 1 volume of oxygen now added, form 2 volumes of oxygen to 1 of nitrogen in the composition of nitrous acid.

A taper will burn in this gas, and phosphorous most vividly. Charcoal also burns in it with a dull red light.

Water dissolves it, and acquires a green tint, which changes to blue, and finally to yellow, as more of the gas is absorbed. The solution is sour, reddens litmus paper, and stains animal substances yellow. It has been called liquid nitrous acid; but with regard to this solution, there is some ambiguity.

Nitric Acid.—This acid may readily be produced by passing the deutoxide of nitrogen *very slowly* into oxygen gas, standing over water. By this operation, four volumes of the former combine with three of the latter; and the compound, therefore, must consist of 2 volumes nitrogen, and 5 volumes oxygen.

The acid as it is formed is absorbed by the water, and it is very doubtful whether it can be exhibited in an insulated state.

The liquid nitric acid is of very great importance in the arts, and is used in large quantities. It is procured, for commerce, by distilling nitre with strong sulphuric acid: the product is an intensely acid liquid, which, when pure, is colourless, and when most concentrated has a specific gravity of 1.5; that is to say, it is by half heavier than water. In this state it contains 25 per cent. of water; which is the least quantity with which it is known to exist.

In the plate, Acids' *Manufacture*, is given a view of the apparatus employed in preparing this acid. A is a large iron pot with earthenware head and plug at *f*. Two iron vessels receive the acid, and are provided with earthenware stop-cocks. The iron vessels are united by the pipes *c e*, and a third vessel containing a safety-pipe *l*, dipping in water, completes the apparatus.

In this state it is called *hydro*-nitric acid (from a Greek word, signifying water), to denote this combination. In entering into other compounds, it abandons the water and combines in the dry, or, as it is termed, the *anhydrous* state.

It may be *mixed* with water in any proportions beyond the 25 per cent.

The nitric acid is a highly corrosive fluid, and acts as a powerful cautery when applied to the skin, which it stains of a permanent yellow. It is decomposed, with great violence, by most substances which have an affinity for oxygen; which element enters so largely into its composition. If it be brought into contact with hydrogen, at a high temperature, a violent detonation will be the consequence; but the experiment is dangerous, and should not be made without great caution. When poured upon warm, dry charcoal in powder, combustion ensues, with the emission of copious fumes of deutoxide of nitrogen. Spirits of turpentine may be inflamed by suddenly pouring nitric acid upon it: the acid should be poured out of a phial attached to a long stick, or there would be danger to the eyes of the operator.

Muriatic Acid.—Chlorine and hydrogen may be mixed together; and if carefully excluded from the light of day, will remain without change. If the mixture be made with equal volumes of the two, and exposed to light, they will gradually combine; the chlorine will lose its peculiar colour and smell, and a powerfully acid gas will result, without any change of volume. If the mixture be made in a stout phial, with a well-fitted stopper, secured by wrapping a cloth round the neck, and exposed to the direct rays of the sun, the combination will take place suddenly and with detonation. When the stopper is afterwards withdrawn under mercury, it will be found that no condensation has taken place; but if under water, it will instantly rush in and fill the phial, as the new compound is rapidly absorbed by that liquid. The mixture may also be exploded by flame or the electric spark.

To this compound the name of muriatic acid has been given, and it is sometimes called hydrochloric acid. As the elements combine without condensation, its specific gravity must be the mean between those of its two ingredients.

Carbonic Acid.—Carbonic acid is most conveniently obtained by dropping fragments of marble or chalk into muriatic acid, diluted with two or three times its weight of water. A strong effervescence ensues, the gas from which may be collected over the water-bath.

This gas is colourless and inodorous. It is rather more than by one-half heavier than common air; 100 cubic inches weighing 46.5 grains. It is perfectly uninflammable, and instantly extinguishes flame. From its great specific gravity, it will remain for some time at the bottom of a jar with its mouth turned upwards; and may be poured from one such vessel into another like water. It is an amusing experiment to place a lighted taper in the bottom of the jar, as it will be instantly extinguished by pouring the gas upon it, like a liquid.

It is speedily fatal to animals which breathe it: and hence the danger of exposure to the fumes of burning charcoal, which have in so many instances proved fatal. From its great density, it also not unfrequently collects in the bottoms of wells and mines, while the upper parts are free from it, and, from its injurious effects, is called by the miners *choak damp*. It has been condensed into a liquid by a pressure amounting to that of 36 atmospheres, or a column of mercury 90 feet in height.

Water, under common circumstances of pressure

and temperature, will dissolve about its own bulk of this gas; but the quantity taken up may be increased by pressure, and will, in fact, be in exact proportion to the compressing force. It is by the strong compression of a forcing-pump that the common soda-water is so highly charged with this gas.

The solution has an agreeable subacid taste, and reddens paper stained with the blue colour of litmus. When, however, an infusion of litmus, which has been reddened by this acid, is boiled, the blue colour returns as the acid escapes; an effect which distinguishes it from all other bodies of the same class. The pleasant pungency of brisk and sparkling fermented liquors is owing to the carbonic acid which they hold in solution, and which they lose upon exposure to the air, and become thereby flat and stale.

Carbonic acid is produced in all the common cases of combustion, and is likewise abundantly formed during the respiration of animals; it is not, therefore, surprising that it should be always present in the atmosphere to the amount of about one-thousandth or one-fifteen-hundredth of its bulk. Indeed, the great wonder is, considering the abundance of its sources, that it does not accumulate to a greater extent.

Pyroligneous Acid.—This very important acid body is procured by the distillation of wood in iron retorts. Great quantities of pyroligneous acid is collected with little or no trouble during the preparation of charcoal for gunpowder; but it is empyreumatic and impure, and several processes have been contrived to free it from tar and other matters which it contains. It may be saturated with chalk, and evaporated, by which an impure acetate of lime will be obtained, and which mixed with sulphate of soda furnishes, by double decomposition, sulphate of lime and acetate of soda: the latter, distilled with sulphuric acid, produces the acetic acid of commerce.

A very perfect apparatus, combining the manufacture of charcoal with that of pyroligneous acid, is shown in plate Acids' *Manufacture*. A is the worm or condensing tub placed in the centre of the figure, and B, the retort furnace. The wood is introduced at the doors *b b*, and the carbonization effected by fire applied beneath, the chimney C being employed to carry off the vapour. The impure pyroligneous acid passes by the pipe *p* into the worm tub A, and from thence into the large receiver D. The carburetted hydrogen gas, and other uncondensable matter passes off by the bent tube *f g*.

Pyroligneous acid is now employed to a considerable extent in the preservation of meat. In this case the rough acid is found to impart the same flavour to pork and mutton which they would derive from a previous smoking, so that they at once become converted into ham.

Hydro-Fluoric Acid.—There is a substance well known in mining districts, called *fluor spar*. It is found crystallized in cubes of various colours, green, yellow, and purple; and a compact variety of the same substance, the product of Derbyshire, is worked into splendid ornamental vases. If this mineral be reduced to powder, mixed with twice its weight of strong hydro-sulphuric acid, and subjected to distillation, a powerful and highly corrosive liquid acid may be obtained. For this purpose a leaden or silver retort and receiver must be employed; and while a moderate heat is applied to the former, the latter must be kept cool by pounded ice or snow. The hydro-fluoric acid thus formed must be preserved in silver or leaden bottles, with stoppers of the same materials. It is extremely volatile, and not easily confined. In appearance it resembles oil of vitriol. Its specific gravity, when first prepared, is 1.06, but is increased by the gradual addition of water to 1.25; and there is no known instance of a similar condensation. It is necessary to use great caution in experimenting with this substance, as its vapours are highly irritating, and, when applied to the skin, it disorganizes it so rapidly as to occasion dangerous ulcers. In addition to the usual properties of a powerful acid it acts strongly on glass, and corrodes it deeply. Plates of glass, covered with a composition of bees-wax and turpentine, may be drawn upon with a graver, and those parts which are laid bare may be perfectly etched by exposure either to the vapour or the diluted acid.

Hydrocyanic or Prussic Acid.—If a narrow tube be filled with fragments of the saline body called cyanuret of mercury, and placed in a horizontal position, when a stream of sulphuretted hydrogen gas is passed through it, a double decomposition ensues: the sulphur of the gas combines with the metal, black sulphuret of mercury is formed, and the cyanogen which is liberated enters into a new combination with the hydrogen. The product may be expelled by a very gentle heat, and collected in a receiver kept cool by ice. A similar product may be obtained by moistening the cyanuret of mercury with muriatic acid, and distilling at a low temperature. The hydrocyanic acid thus obtained is a colourless liquid, possessing a strong odour resembling that of peach blossoms. In its pure state it is intensely poisonous, and a single drop of it placed upon the tongue of a dog causes almost instant death. When greatly diluted with water, it has the taste of bitter almonds, which, in fact, owe their flavour to a small portion of this acid. Water distilled from the leaves of the laurel also derives its poisonous quality from the presence of the same ingredient. The vapour of the pure acid takes fire on the approach of flame, and when mixed with oxygen gas detonates with the electric spark. It is extremely volatile, and boils at 79° Fah.; and at 0° it congeals. When a drop of it is suffered to fall upon a piece of glass it becomes solid; the cold produced by its rapid evaporation being sufficient to freeze what remains. Hydrocyanic acid reddens litmus paper feebly, and forms salts with the different salifiable bases. Owing to the tendency of its component elements to form other arrangements, it is very liable to spontaneous decomposition, and it is not easy to preserve it from change even out of the contact of the air in well-stopped bottles. The diluted acid is sometimes used in medicine, and it may be proper to add that an itinerant exhibitor of chemical experiments, named Chaubert, has lately been in the habit of swallowing large quantities of what he called prussic acid without producing any fatal effects.

Acidulous, in *Chemistry*, slightly acid.

Acnua, a Roman measure of land equal to about a quarter of an English acre.

Acoustics. One of our most important connexions with external objects is maintained through the sense of hearing; that is, by an affection which certain actions or motions, in those objects, produce on the mind, by being communicated to it through the ear. The peculiar excitation or motion perceptible by

the ear is called *sound;* and the consideration of this motion, its qualities and transmission, forms the science of acoustics. Philosophers distinguish between sound and noise: thus those actions which are confined to a single shock upon the ear, or a set of actions circumscribed within such limits as not to produce a continued sensation, are called a *noise;* while a succession of actions which produce a continued sensation are called a *sound.* It is evident from the mechanism of the ear, so far as it is understood, that it is a refined contrivance for conveying a motion from the medium which surrounds it to the auditory nerve; and that this nerve must receive every motion excited in the tympanum. Every motion thus excited, however, does not produce the sensation of sound. That motions may be audible, it is necessary that they impress themselves upon the medium which surrounds the ear with velocities comprised within certain limits. These motions are commonly produced by disturbing the equilibrium which exists between the parts of a body. Thus, for example, if we strike a bell, the part which receives the first impulse of the blow is driven nearer to the surrounding parts; but, the impulse having ceased, it is urged back by a force of repulsion which exists in the metal, and made to pass beyond its former position. By the operation of another property of the metal, namely, cohesive attraction, it is then made to return in the direction of its first motion, again, beyond its position of repose. Each of these agitations influences the adjacent parts, which, in turn, influence those beyond them, until the whole mass assumes a tremulous motion; that is, certain parts approach to and recede from each other; and it only recovers its former state of repose, after having performed a number of these sonorous vibrations. It is evident that such vibrations as are here described must result from the combined operation of attraction and repulsion, which, together, constitute the elasticity of solid bodies. When fluids, whose elasticity is confined to repulsion, emit sounds, a force equivalent to that of attraction in solids is supplied to them by external pressure. The sonorous vibrations of bodies are exceedingly curious, and the more difficult to be understood from our habits of measuring changes or motions by the sight; but these motions affect very sensibly another organ, while they are almost imperceptible to the eye; and, as we are without the means of converting the ideas derived from one sense into those derived from another, the sensation of the motion of sound does not assist us to understand its precise nature, as compared with visible motions. Thus, the ear at once perceives the difference between a grave and an acute sound; but it is only from attentive observation by the eye, that we discover the different rapidity of succession in the vibrations which produce them. The vibrations of a great many bodies, as strings, bells, and membranes, when emitting sounds, may, however, be distinctly seen, and even felt; but they may often be rendered more sensible to the eye by a little artifice, such as sprinkling the vibrating body with sand, or some light, granular substance.

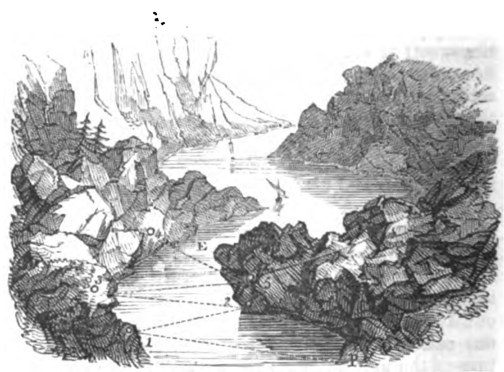
Sound may be produced without vibrations or alternations; thus, if we pass the nail quickly over the teeth of a comb, the rapid succession of single shocks or noises produces all the effect of vibrations. It must be evident that the rapid motions here described, whether originating in vibrations, or a succession of concussions, must be communicated from the body, in which they are excited, to the sheet of air, or whatever else be in contact with it, and from this again to another sheet beyond the first; thus diffusing the motion in every direction. The agitation of the sounding body must thus be communicated to the surrounding medium to a great distance, and impressed upon any body situated within this distance; if this body be the ear, the tremor excited in it by these agitations will be perceived by the mind. The necessity of some medium for the transmission of sound is proved by experiment. If a bell be rung in an exhausted receiver, the sound will be hardly perceptible, while the tones will become clear and distinct, on re-admitting the air.

Having thus given a general outline of the source and propagation of sound, we shall proceed to consider some of the more important facts connected with them.—The most obvious characteristics, by which we distinguish different sounds, consist of differences in their degrees of what we call loudness, and acuteness, or *pitch.* We can produce, at pleasure, sounds having different degrees of loudness, from the same sonorous body, by making the concussions upon it more or less violent; disturbing in a greater or less degree the arrangement of its parts. So two bodies of like substance and figure, but unlike mass, when subjected to the same shock, emit sounds unlike in loudness; and, again, bodies of like mass and figure, but unlike substance, form sounds more or less loud, when subjected to the same shock. In this latter case, the loudness has a relation to the quantity of elasticity possessed by the bodies; and in all cases, when the disturbance of the parts is carried beyond the elastic power of the body, so as to produce a permanent change of figure, no increase of loudness is induced. From a consideration of the preceding facts, we may conclude, that loudness depends upon the quantity of motion, or sonorous vibration, in which it originates. The other principal characteristic of sound, its acuteness or pitch, depends upon the frequency with which the concussions or vibrations of the sonorous body succeed each other. That sounds may be audible to a common ear, it is necessary that the concussions upon the medium, which communicates them, should follow each other in such succession, that not more than 8192, nor less than 32, distinct concussions shall be made upon the medium during the lapse of one second. Some ears, however, can perceive sounds emanating from vibrations a little beyond the extremes to which the perceptions of other ears are confined. We should be careful not to confound the frequency of vibrations with the velocity of vibratory motion. A string may vibrate with a greater or less velocity, as it passes its axis to a greater or less distance; yet the times of its vibrations may be all equal. The difference of velocity, affecting the quantity of motion only, would produce no change, except in the loudness of the sound. To those sounds which proceed from infrequent vibrations, we give the name of *grave* or *low;* those from frequent vibrations we call *sharp* or *acute.* When vibrations succeed each other in equal times, their sound excites a pleasant sensation, and they are called *musical.* When two bodies are made to sound together, if their vibrations are performed in equal times, the sounds are said to be in *unison.* When the vibrations are performed in unequal times, so that some of those of the one are not accompanied by those of the other, the ear perceives a degree of dissonance in the sounds.

If, however, the vibrations meet after short and regular intervals, the dissonance is not easily detected, and the sounds are said to *accord*. During the continuance of most primary sounds, however excited, we perceive other and more acute sounds, co-existing with them. These are called their *harmonics*. They are supposed to originate in a series of secondary vibrations, more short and frequent than the principal vibration. Thus a sounding string, for example, may be supposed not to pass its axis in a simple curve, but to resolve itself into a torturous line, formed by a number of smaller curves, each of which vibrates across its own axis, thus producing its harmonics. It is perhaps some combination of the harmonics with the primary sound, that characterizes the sound of different instruments, though of the same loudness and pitch, so that we can distinguish one from another.

The air, being the common medium which surrounds the ear, is that by which sounds are usually transmitted. This transmission is performed with a velocity of about 1130 feet in a second. All other bodies, however, are capable of transmitting sound. It may be done perfectly, even by the solid parts of the head. If, for example, we hold the stem of a watch between the teeth, and cover the ears with the hands, the beats are heard more distinctly than when the instrument is held at an equal distance in the air. The rubbing together of two stones under water may be heard, by an ear in the same medium, at the distance of half a mile. When the air, or any other body of indefinite extent, is disturbed, in a point situated within it, by a sonorous vibration, it forms a wave which passes from the disturbed point, as a centre, in every direction. It follows that as the wave extends itself, the mass to be put in motion increases until the original motion is rendered insensible from the magnitude of the mass to which it has communicated itself. The velocity with which waves, thus formed, move through any homogeneous elastic medium, is always equal to that which a heavy body would acquire by falling through half the height of the modulus of elasticity.* In applying this law to the transmission of sound by the air, it was for a long time found not to give the same results as were obtained by experiment. The discrepancy, however, has been most ingeniously reconciled by a small correction for the latent heat made sensible by the compression; the effect of this being to increase the height of the modulus of elasticity. We ought, therefore, to find that liquids, and more especially some of the solids, should transmit sound much more rapidly than air; and this agrees most perfectly with various experiments. Cast-iron, for example, has been found to transmit sound with a velocity $10\frac{1}{2}$ times greater than air. Sound does not readily pass from one medium to another; a sound made in the air is not easily distinguished under water, although the distance be very small. It is from this, probably, that cork and all soft cellular bodies are bad conductors of sound, as in these the sound must, in passing through the walls of the cells and the air contained in them, change successively from one medium to another. All sounds, whatever be their loudness or pitch, are transmitted with the same velocity; a fact most completely proved by every musical performance. Were it otherwise, indeed, this beautiful art could not exist. To make this apparent, it is only necessary to consider, that harmony is a combination of different sounds, arranged with certain relations of time and pitch. Now, if one sound were transmitted with greater velocity than another, these relations would differ at different distances, or be confounded, except at a single given point. Nay, further; melody, which is a succession of single sounds, would not reach different ears with the same relations of time, if the different notes were not transmitted with equal velocities. Some observations on sound, in very high latitudes, seem to contradict the above law of transmission. The seeming anomaly, however, is sufficiently reconciled by supposing the different strata of air, through which the sounds, in those instances, were transmitted, in very different hygrometrical or thermometrical states, which would make corresponding differences in their modulus of elasticity. When a wave of sound meets an elastic surface, it is partly transmitted and partly reflected. This reflection, when it returns back perpendicularly, is called an *echo*. That an echo may be distinctly heard, it is necessary that the reflecting surface be at such a distance that the original sound shall have ceased before the reflected one returns to the ear; otherwise they will be blended, and the echo not perceived.

One of the most singular and distinctly marked illustrations of the reflection of sound forming a natural echo, occurs on the banks of the Rhine near Lurley. By referring to the accompanying picturesque illustration, the reader will readily understand how the reverbrations of sound are produced.



P, is considered as the phonic centre, the primary point of radiation for the sound, and the waves striking at the first series of numerals, are reflected to twenty, and so on through the series of reflecting points. Dr. Granville's account of this natural phenomenon, is accompanied by such just remarks on the improved views of science now promulgated, even in the humblest classes of society, that it cannot but prove acceptable to our readers. Between St. Goar, and the ruins of Schonberg, at a spot where the Rhine, from the direction of its deep sinuosities, assumes the appearance of successive and isolated island lakes, bounded all round by upright gigantic rocks, or sloping hills, clad with vines to their very summits: the postilions suddenly checked their career, and turning the wide end of their bugles to the reach of the river we had just passed, blew loud and strong their post-boy tune, and then held their breath. Quickly the musical sounds were

* The height of the modulus of elasticity of air is 27,800 feet.

heard repeated once in a clear and distinct manner, not far from us; and again, a second and a third, and even a fourth time, but as if from a progressively increasing distance, until they died away. The experiment more than once repeated, proved equally successful. We were assured that the repetitions of the sound are more numerous when the experiment is made in a boat placed midway between the two banks.

It is not to be expected that so remarkable and striking a phenomenon should go without being converted into an allegorical tale, during the ages of ignorance and superstition. How, in fact, was this never-failing repetition of the fisherman's choired morning prayer and evening song, which some invisible voice responded in the distant space as he glided over the bosom of the water, to or from his daily toil, to be accounted for? Imagination, ever ready to plunge into the supernatural, created a lovely nymph, and placed her abode on the rock of Lurley, from the sides of which the sounds are principally reverbrated. A dangerous eddy lies on the broad shadow of this rock, and many a time, when the amazed boatman tracked his way through the stream, listening to the mysterious voice from the height of Lurley, his frail bark drawn within the vortex, would miserably perish under the rocky dwelling of the syren. Attracted by the reports of her beauty, and spurred on by the proclaimed cruelty of her disposition, the youthful son of the Count Palatine, of a neighbouring country, determined on seeing the virgin of Lurley, and carrying her a captive to his father's court. His fate was sad; for on arriving, escorted by a few followers, in the agitated waters of Lurley, his boat whirled round and disappeared. Grieved at the loss of his child, the Palatine count dispatched a trusty band to seize the relentless nymph; and just as their rude leader, unmoved by her heavenly charms and dishevelled tresses, was in the act of summoning her to surrender, a sudden hurricane swelled the stream, the waves, crested with foam, rose to the top of the rock, and encircling the lovely Undine, saved her from the rude grasp of man, and carried her to the realm of her fathers. Her voice is still heard returning the song of merriment or sorrow, but her beauteous form appears not on the heights of Lurley.

In this short legend we can trace the working of the mind, under the influence of the heart. Those were not times for the march of intellect, but for that of the passions. Hence the Age of Romance. But now that the heart has lost its influence on the actions of men, under the management of societies for diffusing useful knowledge, and of mechanical institutes—now that the sixpenny treatises on natural philosophy, on hydraulics, and acoustics, all perspicacious and free from errors, enable the commonest understanding to explain on the simplest principles what was before a complicated phenomenon—the echo of Lurley would be accounted for by the singular disposition of the two elevated banks of the river, following parallel lines in a serpentine direction—thus presenting to the rays of sound more than one reflecting surface. This disposition of the two banks, which are here in some parts scarcely more than 1,000 feet asunder, while it accounts likewise for the formidable eddies which are observed in this place, explains how intricate and dangerous the navigation must necessarily be; nay, fatal too, if the careless boatman, less watchful of his course, passes his time in calling on Lurley to repeat his "halloos."

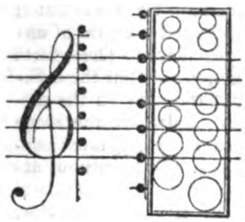
The science of acoustics, like the other physical sciences, has been in a constant state of advancement since the revival of learning. It appears that Pythagoras knew the relation between the length of strings and the musical sounds which they produce. Aristotle was not only aware of this relation, but, likewise, that the same relation subsists between the length of pipes and their notes, and that sound was transmitted by the atmosphere. This constituted the sum of ancient learning in this branch of science. These facts were taught by Galileo, and, moreover, that the difference in the acuteness of sounds depends on the different frequency of vibrations, and that the same string, if of uniform thickness and density, must perform its vibrations in equal times. But, without attempting a history of modern discoveries in acoustics, we can only mention, that the names of Taylor, Moreland, Newton, Daniel Bernoulli, D'Alembert, Euler, Robison, Lagrange, Laplace, Chladni, T. Young, and Biot, are all connected with it. Of these, Newton gave the law of transmission, which we have stated in this article; and the correction for heat was made by Laplace.

The vibrations immediately dependant on elasticity are those of rods, plates, rings, and vessels. These admit of much greater variety, and are of more difficult investigation than the vibration of chords. A rod may be either wholly loose, or fixed at one end only, or at both; and it may either be loosely fixed, in situation only, or firmly fixed, in direction as well as in situation; and these conditions may be variously combined with each other; the rod may also have a variety of secondary vibrations besides the principal or fundamental sound. All these cases have been examined by various mathematicians; the subject was begun by Daniel Bernoulli, and much extended by Euler, some of whose conclusions have been corrected by Riccati; and Chladni has compared them all with experiment. The sounds produced by the same rod, either under different circumstances, or as harmonics which may be heard at the same time, are scarcely ever related to each other in any simple proportion, except that when a rod is loosely fixed at both ends, the frequency of the vibrations of the subordinate notes is expressed by the series of the squares of the natural numbers, as 1, 4, 9, and 16. But the times occupied by any similar vibrations of rods, similarly circumstanced, are always directly as the squares of their lengths, and inversely as their depths. When the rod is wholly at liberty, two, at least, of its points must be at rest, and these are at the distance of about one-fifth of its length from either end, in the next sound of the same rod, the middle point is at rest, with two others near the ends. There is by no means the same regularity in the progress of the vibrations of rods of different kinds, as in those of chords; it can only happen in particular cases, that the rod will return after a complete vibration to its original state, and these cases are probably such as seldom occur in nature.

The vibrations of rings and of vessels are nearly connected with those of plates, but they are modified in a manner which has not yet been sufficiently investigated. A glass or a bell divides, in general, into four portions vibrating separately, and sometimes into six or eight; they may readily be distinguished by means of the agitations excited by them in a fluid

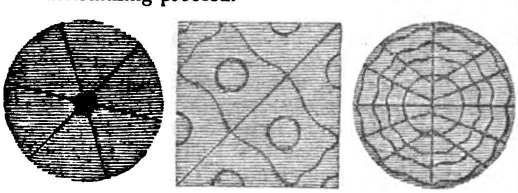
contained in the glass. It is almost unnecessary to observe, that the fluid thus applied, by adding to the mass of matter to be moved, makes the vibration slower and the sound more grave.

Vessels formed of glass are sometimes so arranged as to form a very pleasing musical instrument, and the editor generally uses one in his public lectures, in which the glasses are tuned by grinding their convex surfaces beneath.



The arrangement of the glasses, as originally suggested by Dr. Arnott, is shown in the accompanying figure. The small open circles represent the mouths of the glasses standing in a mahogany case, and the relation of the glasses to the written musical notes, is shown by the common music lines and spaces which connect them. The learner discovers immediately that one row of the glasses produces the notes written upon the lines, and the other row, the notes between the lines; and he is mentally master of the instrument by simple inspection. This arrangement also renders the performance easy, for the notes most commonly sounded in succession are contiguous: and the relations of the notes forming a simple air are so obvious to the eye, that the theory of musical combination and accompaniment is learned at the same time. The set of glasses here represented has two octaves, and the player stands at the side of the case with the notes ascending towards the right hand, as in the piano-forte.

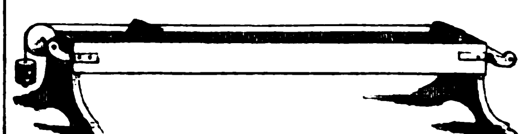
The vibration of plates differs from those of rods in the same manner as the vibrations of membrane, differ from those of chords, the vibrations of which cause the plate to bend in different directions, being combined with each other, and sometimes occasioning singular modifications. These vibrations may be traced through wonderful varieties by Professor Chladni's method of strewing dry sand on the plates, which, when they are caused to vibrate by the operation of a bow, is collected into such lines as indicate those parts which remain either perfectly or very nearly at rest during the vibrations. Dr. Hooke had employed a similar method, for showing the nature of the vibrations of a bell, and it has sometimes been usual in military mining, to strew sand on a drum, and to judge, by the form in which it arranges itself of the quarter from which the tremors produced by countermining proceed.



The above figures show some of the least complex arrangements produced by water on a glass plate—the plate being put into vibration by a violin bow. If a screen be placed a few feet higher than the plate, and a strong light beneath, the figures may be rendered visible to a large audience.

It usually happens that the vibration of a cord deviates from the plane of its first direction, and becomes a rotation or revolution which may be considered as composed of various vibrations in different planes, and which is often exceedingly complicated. These vibrations may be combined, in the first instance, in a manner similar to that which has been already explained respecting the vibrations of pendulums; and if the motion of the chord be supposed to follow the same law as that of a pendulum, the result of two entire vibrations thus united, may be either a vibration in an intermediate direction, or a revolution in a circle or in an ellipsis. But, besides these compound vibrations of the whole chord, it is also frequently agitated by subordinate vibrations, which constitute harmonic notes of different kinds, so that the whole effect becomes very intricate; as we may observe by a microscopic inspection of any luminous point on the surface of the chord; for instance, the reflection of a candle in the coil of a fine wire wound round it. The velocity of the motion is such, that the path of the luminous point is marked by a line of light, in the same manner as when a burning coal is whirled round; and the figures thus described, are not only different at different parts of the same chord, but they often pass through an amusing variety of forms during the progress of the vibration; they also vary considerably according to the mode in which that vibration is excited.

A very useful instrument for ascertaining the effects of length and pressure, with reference to a vibrating string, is shown in the figure. The string is firmly attached at one extremity to the projecting arm, and passing over a bridge somewhat nearer to the centre, is strained by the weight and pulley at the opposite end. A second moveable bridge is seen near the pulley by which the length is regulated.



Under the head of *organ-pipe*, we purpose giving the theory of wind instruments generally; but the following collection of curious facts, bearing upon the general principles of acoustics, are too important to be omitted in our general view of the science.

The resonances of sound, or reciprocated vibrations of columns of air, has been fully examined by Mr. Wheatstone, and we cannot do better than give the result of his observations on this interesting part of acoustics. An elastic body may be made to assume a vibratory state in two ways; either immediately, by any momentary impulse, which altering the natural positions of its particles, allows them afterwards to return by a succession of isochronous oscillations to their former state; or secondarily, by means of an immediately sounding body, which causes it to reciprocate to the latter, when certain conditions, on which depends its susceptibility of vibrating in such a manner, are fulfilled. This reciprocation to which, where the effect is referred to, the term *resonance* is applied, is effected by means of the undulations which are produced in the air, or in any fluid or solid medium, by the periodical pulses of the original vibrating body; these undulations being capable of putting in motion all bodies whose pulses are coincident with their own, and consequently with those of the primitive sounding body. Galileo observed, that a heavy pendulum might be put in mo-

tion by the least breath of the mouth, provided the blasts be often repeated, and keep time exactly with the vibrations of the pendulum; and this remark affords a correct explanation of the phenomenon.

Some of the most obvious cases of resonance are—the vibrations of a string when another tuned in unison with it is made to vibrate; the resounding of the drinking-glass to the sound of the voice, or of a musical instrument; the reciprocated vibrations of a sounding-board, communicating immediately with a vibrating string or tuning-fork, &c. In the last-mentioned instance, though the string and the fork are the original vibrating bodies, the audible sound is dependent on the resonance of the sounding-board.

If one of the branches of a vibrating tuning-fork be brought near the embouchure of a flute, the lateral apertures of which are stopped so as to render it capable of producing the same sound as the fork, then the feeble and scarcely audible sound of the fork will be augmented by the rich resonance of the column of air within the flute. The sound will be found greatly to decrease by closing or opening another aperture; for the alteration of the length of the column of air in such case renders it no longer proper to reciprocate perfectly the sound of the fork. This experiment may be easily tried on a concert flute, with a C tuning-fork. To ensure success, it is necessary to remark, that when a flute is blown into with the mouth, the under lip partly covering the embouchure, renders the sound about a semi-tone flatter than the sound when the embouchure is entirely uncovered; and as the latter must be unison to that of the tuning-fork, it is necessary, in most cases, to finger the flute for B when a C tuning-fork is employed.

A similar effect may be produced by substituting for the column of air in the flute, the alterable volume of air contained within the cavity of the mouth. Mr. Wheatstone found the sounds of tuning-forks reciprocated most intensely by placing the tongue, &c. in the position for the nasal continuous sound of *ng* (in song), and then altering the aperture of the lips until the loudest sound is obtained.

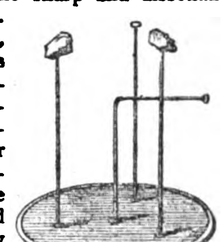
A column of air may also reciprocate a sound originally produced by a wind instrument, as the following experiment will show. Place two concert flutes on a table, parallel to, and at a short distance from each other; on the one which is nearer, sound C sharp (all the lateral apertures being open), and draw out the tube of the second flute, so that it shall be about a semi-tone flatter, to make it equivalent to the flattening of the first flute by the partial closing of the embouchure by the lip; a material difference will then be distinguished in the intensity of the tone by alternately closing and opening the first hole of the more distant instrument, thereby rendering it incapable or capable of reciprocating the original sound. That this effect is occasioned solely by the transmission of the sonorous undulations, and not by any wind actually blown into the second flute is evident from the difference being in intensity and not in pitch.

This experiment may be varied by placing the fipple of a flageolet at a short distance from the embouchure of a flute, provided of course, that the columns of air, both in the flageolet and the flute, be capable of producing the same note.

Among the Javanese musical instruments brought to England by the late Sir Stamford Raffles, there is one called the "Gender," in which the resonances of unisonant columns of air are employed to augment the sounds of vibrating metallic plates. Of these plates there are eleven; the sounds correspond with the notes of the diatonic scale, deprived of its fourth and seventh, and extend through two octaves. The mode of vibration of the plates, is that with two transversal nodal lines; and they are suspended horizontally by two strings, one passed through two holes in the one nodal line, and the other through similar holes in the other nodal line of each plate. Under each plate is placed an upright bamboo, containing a column of air, of the proper length to reciprocate the lowest sound of the plate. If the aperture of the bamboo be covered with pasteboard, and its corresponding plate be struck, a number of acute sounds only (depending on the more numerous subdivisions of the plate) will be heard; but on removing the pasteboard, an additional deep, rich tone is produced by the resonance of the column of air within the tube.

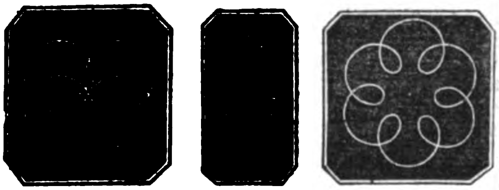
The Gender from which the annexed drawing was taken is at present in the museum of the Honourable East India Company; and there is another specimen in the possession of Lady Raffles.

If a rod be firmly fixed at one end, and allowed to vibrate freely through its whole length, tones of a very peculiar kind are found to result. Thus, a rod only two feet in length will give a tone as deep as that of the bell employed in the church of St. Paul; and the Parisian clock-makers have availed themselves of this fact, in the construction of their ornamental chimney clocks, which, by this means, cost less, and strike without the sharp and dissonant tinkle common to light bells.

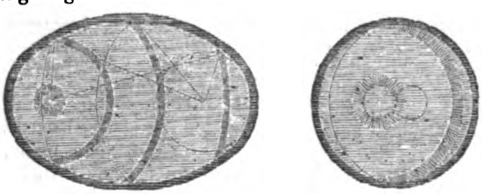


A very pretty instrument, called a "Keleidophone," has been contrived by Mr. Wheatstone, of which the accompanying cut is a representation. It consists of four vibrating rods, on which variously formed bodies are placed, and very beautiful and vivid figures produced by merely drawing either of the rods out of the perpendicular, and then allowing

them to vibrate freely. Quicksilvered glass beads reflect the light of a lamp, or the sun-beams better probably than most other objects; but Mr. Wheatstone showed the editor the letters on a common address card, and which, when attached to a bent rod, produced two most elegant compound figures. The white lines beneath show the paths of a series of these rods.

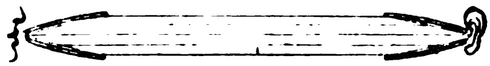


If a sound or a wave be reflected from a curved surface, the new direction which it will assume may be determined either from the condition that the velocity with which the impulse is transmitted must remain unaltered, or from the law of reflection, which requires that the direction of the reflected pulse or wave be such as to form an angle with the surface, equal to that which the incident pulse before formed with it. Thus, if a sound or wave proceed from one focus of an ellipsis, and be reflected at its circumference, it will be directed from every part of the circumference towards the other focus; since the distance which every portion of the pulse has to pass over in the same time, in following this path, is the same, the sum of the lines drawn from the foci to any part of the curve being the same; and it may also be demonstrated that these lines form always equal angles with the curve on each side. The truth of this proposition may be easily shown by a simple experiment on a bason of water; the curvature of a circle differs so little from that of an ellipsis of small eccentricity, that if we let a drop fall into the bason near its centre, the little wave which is excited will be made to converge to a point at an equal distance on the other side of the centre. The effects of these reflections are perfectly illustrated in the accompanying diagrams.



An umbrella held in a proper position over the head, may serve to collect the force of a distant sound by reflection, in the manner of a hearing trumpet; but its substance is too slight to reflect any sound very perfectly, unless the sound fall on it in a very oblique direction. The whispering gallery of St. Paul's produces an effect nearly similar by a continued repetition of reflections. Mr. Charles's paradoxical exhibition of the Invisible Girl has also been said to depend on the reflection of sound; but the deception is really performed by conveying the sound through pipes ingeniously concealed, and opening opposite to the mouth of the trumpet from which it seems to proceed.

The speaking and hearing horns owe their operation to the reflection of sound. The reader has already seen how capable a continuous pipe is of transmitting the waves or pulses of the air. This is also, to a certain extent, accomplished by a trumpet-mouthed vessel, and a second apparatus may be employed to collect the pulses which have thus been transmitted.



The above figure shows at one view the joint effects of both forms of the trumpet. The organs of *voice* and *hearing* will be found under those heads.

Acre, a measure of superficies, and the principal denomination of land-measure in use throughout the whole of Great Britain. The word (formed from the Saxon *æcer*, or the German *acker*, a field) did not originally signify a determinate quantity of land, but any open ground, especially a wide campaign; and in this antique sense it seems to be preserved in the names of places, as Castle-acre, West-acre, &c. The English standard acre, now the imperial acre of Britain, is determined from a square, each of whose sides is the chain of 66 feet, or 22 yards, or 1-80th of a mile. Ten of these squares form the acre, which thus contains 4840 square yards. This is divided into roods, of which there are four in the acre; and into poles or perches, of which there are 40 in each rood, or 160 in the acre. The rood will thus measure 1210 square yards, and the pole 30¼ square yards.

The above is the standard acre of England; but various customary acres are in use throughout the different counties, deviating considerably from this standard both in excess and defect, though all of them are now illegal since the act 5 George IV., which establishes the same standard throughout the whole kingdom. In Bedfordshire, it is sometimes only two roods; Cheshire, formerly, and still in some places, 10,240 square yards; Cornwall, sometimes 5760 yards; Dorsetshire, generally 134 perches; Hampshire, from 107 to 120 perches, but sometimes 180; Herefordshire, two-thirds of a statute acre. The acre for hops contains 1000 plants, and is only equal to half a statute acre; for wood, again, it is 256 perches. Leicestershire, 2308¾ square yards; Lincolnshire, five roods, particularly for copyhold land; Staffordshire, nearly 2¼ acres; Sussex, 107, 110, 120, 130, or 212 perches; the short acre 100 or 120 perches, the forest acre 180 perches. Westmoreland, 6760 square yards, or 160 perches of 6½ yards square; in some parts the Irish acre is used: Worcester, the hop acre, of 1000 stocks, 90 perches, sometimes 132 or 141 perches.

In North Wales, the *Erw* or true acre is 4320 square yards, the *Stang* or customary acre 3240 square yards, as in Anglesea and Caernarvonshire, making 5¼ Llathen, = 160 perches of 4½ yards square, called *paladr:* 8 acres make an *ox-land*, and 8 of these a *plough-land*, in Pembrokeshire. In South Wales the Erw varies greatly with the perch; sometimes this is nine feet square, 160 perches making one stangell, and four stangells one erw of 5760 yards; sometimes 10½ feet square, making a quart or quarter of a llath, 40 of which make a stangell, and four stangells an erw, which is thus 7840 yards, equal to the Irish acre; sometimes 11 feet, called bat or eglwys haw, making the erw 9384 yards, as in Glamorganshire, one-fifth more = 11,261 yards; sometimes 11½ feet, called a llath, 48 making a quarter cyvar, and four

cyvars an erw of 11,776 yards; lastly, 12 feet, giving an erw of 10,240 yards, equal to the Staffordshire acre.

Nothing can show more clearly than the existence of such numerous and useless diversities, the necessity of the late act for establishing a uniform standard throughout Great Britain, and which only requires to be enforced with strictness to abolish for ever every other measure. In Scotland the acre is much more uniform, scarcely deviating in any part more than one per cent. from the standard.

Acroteria, or Acroters, small pedestals usually without bases, placed in the middle and at the two extremities of pediments, and serving also to support statues. The same term was also applied to the figures placed as ornaments on the summits of public edifices.

Action, is that motion which one body produces or endeavours to produce in another. Mechanical action is exerted either by percussion or by pressure; and, in either case, the force exerted by the acting body is repelled in an equal degree by the body on which it acts. Thus, in driving a nail with a hammer, the stroke acts as powerfully against the face of the hammer as against the head of the nail; and in pressing the hand upon a stone, the pressure upon the stone is equally great with that upon the hand. In each of these cases the impulse is counteracted by what is termed the re-action; and that action and re-action are always equal, is not only laid down as an axiom in mechanics, but is understood to be a general law of nature.

Active Force, see *Force*.

Actus, a term used by Vitruvius as a measure of 100 Roman feet in length. It was also applied in agriculture to the length of one furrow, or the distance traversed by a plough in one continued line.

Acupuncture, a surgical operation, which is performed by the insertion into the part affected of a silver or golden needle. It is practised to a large extent by the Chinese and Japanese, who employ it beneficially in cases of headache, lethargy, convulsion, colic, and other maladies. It has been introduced into this country, and resorted to with great advantage, particularly in hydrocephalous diseases, in which Dr. Conquest has employed it with eminent success.

Acute Angle. See *Geometry*.

Acute, in *Music*, is used to express the quality of a tone which is sharp or high in comparison with some other. It is thus opposed to *grave*.

Addition, the first of the four operations of *Arithmetic*, which see.

Additions, in *Heraldry*, are a species of bearings in coat armour, in which are placed rewards or additional marks of honour.

Adductors, an anatomical term, applied to those muscles which draw together the parts into which they are inserted.

Adhesion, according to the latest phraseology of physics, means generally the tendency of heterogeneous bodies to adhere together; but *cohesion* implies the attraction of homogeneous particles of bodies. Adhesion may take place between two solids, as two hemispheres of glass, or between a solid and a fluid, or between two fluids, as oil and water. Thus it is said that a fluid adheres to a solid, as water to the finger dipped into it. But there is a great difference, in this respect, in different bodies; thus small particles of quicksilver do not adhere to glass, but they adhere to gold, silver, and lead, in consequence of chemical attraction. Water adheres to the greatest part of bodies, unless it is separated from their surface by oily substances, dust, flour, &c. Fluids do not form a surface perfectly horizontal in vessels to which they adhere so as to wet them, but rise, on the contrary, around the brim of the vessels. This is proved by fluids poured into glasses, &c. Fluids, on the other hand, in vessels to which they do not adhere, sink around the brim, and rise in the centre. Thus quicksilver in a glass forms a convex surface. This phenomenon of the rising and sinking of fluids becomes still more remarkable in vessels of a small diameter; wherefore capillary tubes, so called, are used for performing experiments, and the singular effects produced are ascribed to capillary attraction.

Adhesion should, strictly speaking, be divided into two kinds. The one, a species of natural attraction which takes place between the surfaces of bodies, whether similar or dissimilar, and which, in a certain degree, connects them together; the other, the joining or fastening together of two or more bodies by the application of external force.

With respect to the first-mentioned, it has been proved, that the power of adhesion is proportionate to the number of touching points; and this, in solid bodies, depends upon the degree in which their surfaces are polished and compressed. The effects of this power are extremely curious, and, in many instances, astonishing.

Musschenbrœck relates, that two cylinders of glass, whose diameters were not quite two inches, being heated to the same degree as boiling water, and joined together by means of melted tallow lightly put between them, adhered with a force equal to 130 lbs; that lead of the same diameter, and in similar circumstances, adhered with a force of 275 lbs.; and soft iron with a force of 300 lbs.

Martin, in the *Philosophia Britannica*, states, that with two leaden balls, not weighing above a pound each, nor touching upon more than one-thirtieth of a square each surface, he has lifted more than 150 lbs. weight; and that the force of adhesion between two brass planes, each four and a quarter inches in diameter, and smeared with grease or fat, was so great, that he never could meet with two men strong enough to separate them by pulling against each other. In the first experiment, the balls were scraped very finely with the edge of a sharp pen-knife, and then equally pressed together with a considerable force and a gentle turn of the hand.

We may now notice the adhesion of nails. Every carpenter is familiar with the use of the nail, and possesses a practical knowledge, more or less accurate, of the force of adhesion of different nails, and in different substances, so as to decide, without difficulty, what number, and of what length, may be sufficient to fasten together substances of various shapes, and subject to various strains. But, interesting as this subject unquestionably is, it has not been till very recently that the necessary experiments have been made to determine, 1st. the adhesive force of different nails when driven into wood of different species; 2d. the actual weight, without impulse, necessary to drive a nail a given depth; and 3d. the force required to extract the nail when so driven. The obtaining this useful knowledge was reserved for Mr. B. Bevan, a gentleman well known in the me-

chanical and scientific world, for the accuracy with which his experiments are conducted.

Mr. Bevan observes, that the theoretical investigation points out an equality of resistance to the entrance and extraction of a nail, supposing the thickness to be invariable; but as the general shape of nails is tapering towards the points, the resistance of entrance necessarily becomes greater than that of extraction: in some experiments he found the ratio to be 6 to 5.

The following table exhibits the relative adhesion of nails of various kinds, when forced into dry Christiana deal, at right angles to the grain of the wood.

Description of Nails used.	Number to the lb. Avoirdupois.	Inches forced into the wood.	Pounds requisite to extract.
Fine Sprigs . . .	4560	0·40	22
Ditto	3200	0·44	37
Threepenny brads .	618	0·50	58
Cast iron nails . .	383	0·50	72
Sixpenny nails . .	73	1·00	187
Ditto	—	1·50	327
Ditto	—	2·00	530
Fivepenny nails . .	139	1·50	320

The percussive force required to drive the common sixpenny nail to the depth of one inch and half into dry Christiana deal, with a cast iron weight of 6.275 lbs., was four blows or strokes falling freely the space of 12 inches; and the steady pressure to produce the same effect was 400 lbs.

A sixpenny nail driven into dry Elm, to the depth of one inch across the grain, required a pressure of 327 pounds to extract it; and the same nail, driven endways or longitudinally into the same wood, was extracted with a force of 257 pounds.

The same nail driven two inches endways into dry Christiana deal, was drawn by a force of 257 pounds; and to draw out one inch, under like circumstances, took 87 pounds only. The relative adhesion, therefore, in the same wood, when driven transversely and longitudinally, is 100 to 78, or about 4 to 3 in dry elm; and 100 to 46, or about 2 to 1 in deal: and in like circumstances, the relative adhesion to elm and deal is as 2 or 3 to 1.

The progressive depths of a sixpenny nail into dry Christiana deal by simple pressure were as follows:

One quarter of an inch, a pressure of	24 lbs.
Half an inch	76 —
One inch	235 —
One inch and half	400 —
Two inches	610 —

In the above experiments, great care was taken by Mr. Bevan to apply the weights steadily, and towards the conclusion of each experiment, the additions did not exceed 10 lbs. at one time, with a moderate interval between, generally about one minute, sometimes 10 or 20 minutes. In other species of wood, the requisite force to extract the nail was different. Thus, to extract a common sixpenny nail from a depth of one inch out of

Dry oak, required . . .	507 lbs.
Dry beech	667 —
Green sycamore	312 —

From these experiments, we may infer that a common sixpenny nail, driven two inches into dry oak, would require a force of more than half a ton to extract it by a steady force.

A common screw, of one-fifth of an inch, was found to have an adhesive force of about three times that of a sixpenny nail.

The force necessary to break or tear out a half-inch iron pin, applied in the manner of a pin to a tenon in the mortice, has likewise obtained the attention of the same ingenious experimentalist. The thickness of the board was 0·87 inch, and the distance of the centre of the hole from the end of the board 1.05 inch. The force required was 979 lbs.

As the strength of a tenon from the pin-hole may be considered in proportion to the distance from the end, and also as the thickness, we may, for this species of wood, obtain the breaking force in pounds nearly, by multiplying together one thousand times the distance of the hole from the end by the thickness of the tenon in inches.

The adhesion of glue is no less important in a practical point of view. Mr. Bevan glued together by the ends two cylinders of dry ash wood, one-fifth of an inch in diameter and about eight inches long; after they had been glued together 24 hours, they required a force of 1260 pounds to separate them; and as the area of the circular ends of the cylinders were 1.76 inch, it follows that the force of 715 pounds would be required to separate one square inch.

It is right to observe, that the glue used in this experiment was newly made, and the season very dry. For in some former experiments on this substance, made in the winter season, and upon some glue which had been frequently made, with occasional additions of glue and water, he obtained a result of 350 to 560 pounds to the square inch.

The present experiment, however, was conducted upon a larger scale, and with greater care in the direction of the resultant force, so that it might be, as near as practicable, in a line passing at right angles through the centres of the surfaces in contact. The pressure was applied gradually, and was sustained two or three minutes before the separation took place.

Upon examining the separated surfaces, the glue appeared to be very thin, and did not entirely cover the wood, so that the actual adhesion of glue must be something greater than 715 pounds to the square inch.

Mr. Bevan also tried the lateral cohesion of fir-wood, from a scotch fir of his own planting, cut down in the autumn, sawn into boards, and at the time of experiment, quite dry and seasoned. The force required to separate the wood was 562 pounds to the square inch; consequently, if two pieces of this wood had been well glued together, the wood would have yielded in its substance before the glue.

From a subsequent experiment, made on solid glue, the cohesive force was found to be 4000 pounds per square inch; from which it may be inferred, that the application of this substance as a cement is susceptible of improvement.

Adipocire, from *adeps*, fat, and *cera*, wax; a substance of a light-brown colour, formed by the soft parts of animal bodies, when kept for some time in water, or when preserved from atmospheric air. When this substance is subjected to a chemical analysis, a true ammoniacal soap is first yielded, composed of ammonia, a concrete oil, and water. The oil may be obtained pure, and this is called more strictly

adipocire. It was discovered on removing the animal matter from the burial ground of the church *des Innocens*, at Paris, in 1787, amongst the masses of the bodies of the poor there interred together. In this place, about 1500 bodies were thrown together into the same pit, and, being decomposed, were converted into this substance. In the crypt, beneath the ancient church of St. Martin-le-Grand, several human bodies have been found converted into adipocire. (See *Nicholson's Journal*, vol. 4, p. 135; *Phil. Trans.* 1794, vols. 84, 85; *Journal de Physique*, tom. 38, &c.)

Adit, the shaft or entrance of a mine.

Adjunct, in *Music*, a term expressive of the relation between the principal mode, and the modes of its two-fifths, which, from the intervals that constitute the relation between them and it, are called its adjuncts.

Adnata, in *Anatomy*, one of the coats of the eye, also called conjunctiva and albuginea.

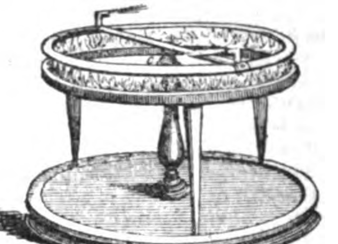
Adustion, a surgical operation of the same nature as cauterization, and consisting in the application of a burning substance to the part affected.

Æginetan Style and Monuments of Art. An association of English and German artists and lovers of the arts was formed in 1811, chiefly with a view of obtaining an architectural survey of the temple of Jupiter Panhellenius, at Ægina, which is one of the most beautiful remains of the Doric architecture. A sketch of this temple may be found in the *Journal of Science*, and in the *Isis*, a periodical edited by Oken, in Germany. This undertaking was amply rewarded by a fine collection of valuable sculpture, which once adorned the eastern and western fronts of that noble edifice. It was purchased by the king of Bavaria in 1812, and the deficient parts restored by Thorwaldson. Every member of the association received a cast of it carefully executed in plaster of paris. These works are valuable as faithful imitations of nature, and for the light which they shed over one of the darkest periods in the history of art. They show that the Æginetan style of art was independent of the Attic. Pausanias calls Smilis the Dædalus of Ægina, assures us that he was the contemporary of Dædalus, and ascribes therefore to the Æginetan style equal antiquity and independence with the Attic. The language and manners of Ægina were Doric; and its sculpture has a Doric character, as distinct from the Attic (which was originally Ionic) as Doric poetry and architecture. The characteristic peculiarity and aim of the Æginetan style is the faithful and exact imitation of nature, carried even to deception. Attic art was a daughter of the Ægyptian, and a striving after the ideal is perceptible in both. To gain a clear idea of primitive art, we must distinguish between the Ægyptian, ancient Attic, Æginetan, and Etrurian styles. Rudeness, stiffness, and meagreness belong to the first attempts in every art. In other respects, they differ from one another, although, at a later period, they exercise a mutual influence. The perfection of art in Phidias has hitherto appeared almost a miracle; but we now comprehend how the Æginetan school, imitating nature with almost perfect exactness, pointed out the way to the ancient Attic, teaching it to rise from the abstract to the living, from the conventional to the natural. Thus we find the long-desired link of connexion between the ancient severe and beautiful styles. Since the creations of Phidias, the traces of the proper Æginetan style have disappeared. There was subsequently, therefore, only one perfect style of art, which spread over all Greece; and *Æginetan* became the name for primitive sculpture. Smilis was the father and founder of the Æginetan style of art; next to him came Callon, who lived between the 60th and 70th Olympiads (540—500 B. C.) About the time of Phidias, there lived the following masters, famous in this style: Anaxagoras, who made the Jupiter which was placed in Olympia at the common expense of all the Greeks, who fought victoriously at Platæa, B. C. 379; Simon, the maker of the consecrated offering of a certain Phormis at Olympia; and Glaucius and Onatas, who flourished in the 78th Olympiad. The Æginetan figures now exhibited at Munich are 17. They may be divided into 4 classes: 1, upright, clothed, and female; 2, advancing or fighting combatants; 3, kneeling, or archers; 4, lying, or wounded. The largest of these figures is Minerva. She is a little above the human size; all the others are rather below this measure. If we consider the style of these works, there prevails in every part of the bodies, the head excepted, a minute imitation of nature, without the least traces of the ideal. Still the imitation is neither poor nor offensive to the rules of art, but a good copy of beautiful nature, with the most perfect knowledge of the bones and muscles. With respect to proportion, these figures are slender, rather small at the hips, and the legs remarkably long. There is much life in the attitudes, though they are not altogether free from a certain stiffness, such as may be observed in the paintings of Giotto, Masaccio, Perugino, &c. The heads seem to belong to an earlier epoch of art; the eyes project, and are lengthened somewhat in the Chinese fashion; the mouth has prominent lips, with well marked edges; the corners in some are turned up; the nose is rather small; the ears finished with the greatest care; the chin is full, and generally too large. They all look alike, and exhibit not the slightest expression of passion; between conquerors and conquered, gods and men, there is not the least difference. The appearance of the hair is not natural, but stiff and conventional. The arms are rather short; the hands natural to deception; not a wrinkle of the skin is forgotten. The legs are well shaped; the knees masterly; the feet elegant; and the toes, which are rather too long, run out parallel. The drapery is close to the body, with folds artificially arranged. Though the style is hard, the execution is tasteful and elaborate. They were apparently made at the same time, but not by the same artist. No one of them has any support, and they are equally finished on all sides. The number of figures originally amounted to 30, at least. They were symmetrically arranged on both fronts of the temple. The Minerva stood in the middle, the standing warriors next, then the archers, and the lying figures last. The temple was not intentionally destroyed, but was probably thrown down by an earthquake. Since Æacus erected this temple to Jupiter Panhellenius, it is probable that the figures represent the battles of the Æacidæ, under the protection of Minerva. The two contests in which the Æacidæ distinguished themselves most gloriously, were the Trojan war and the naval battle of Salamis: in the latter, the images of the Æacidæ of Homer, Ajax, and Telamon, were displayed, and regarded as supernatural protectors. According to another opinion, the group of the eastern front represented the contest around the body of Laomedon, king of Troy and the

one on the western, that around the body of Patroclus. The figures should probably be assigned to a period between the 60th and 80th Olympiads. Pindar calls Ægina the "well-fortified seat of the Æacidæ," probably referring to these images, for no one of the sons of Æacus then remained in the country. The marble of which they are wrought is Parian, of the kind usually called *Grechetto*. The colours perceptible here and there on the figures are vermillion and azure. All the decorations and foliage of the temple, which are generally carved, were painted. The niches of the fronts in which these figures stood were azure, the partitions red, the foliage green and yellow, and even the marble tiles were painted with a kind of flower. We cannot call this system of painting barbarous; we find it even on the Parthenon. Winckelmann was the first who conjectured the existence of an ancient school of art in Ægina, from the accounts of Pausanias. (See *Wagner's Bericht uber die Æginetische Bildwerke, herausgegeben und mit kunstgeschichtlichen Anmerkungen begleitet, von Schelling*, 1817; *Wagner's Report on the Æginetan Remains of Art*, &c.) Subsequently, K. Otfr. Muller, in his learned and acute work, *Æginæticorum Liber*, Leipsic, 1820, attempted to determine their relation to the other monuments still extant; and Thiersch to investigate their mythological signification. Against the idea of a peculiar Æginetan style of art, deduced from these marbles, Henry Meyer wrote in Goethe's *Kunst und Alterthum*, 3 *Bd*. 1. *Heft*., and opposed the derivation of Grecian sculpture from the Egyptian as strenuously as Winckelmann advocated it.

ÆOLIAN HARP, or ÆOLUS'S HARP, was introduced into England about the middle of the last century. It is generally a simple box of thin fibrous wood (often of deal), to which are attached a number of fine catgut strings, sometimes as many as 15, of equal size and length, and consequently unisons, stretched on low bridges at each end. Its length is made to correspond with the size of the window or other aperture in which it is intended to be placed; its width is about five or six inches, its depth two or three. It must be placed with the strings uppermost, under which is a circular opening in the centre as in the belly of the guitar. When the wind blows athwart the strings, it produces the effect of a choir of music in the air, sweetly mingling all the harmonic notes, and swelling or diminishing the sounds according to the strength or weakness of the blast. A more recent Æolian harp, invented by Mr. Crossthwaite, has no sounding-board, but consists merely of a number of strings extended between two deal boards. The invention of the Æolian harp has been generally ascribed to father Kircher, but the fact is, that it was known and used at a much earlier date in the East, as Mr. Richardson has proved, in his *Dissertation on the Manners and Customs of the East*.

ÆOLIPILE. This instrument was employed for domestic purposes at a very early period. It usually consists of a spherical ball of metal, with a pipe of small bore through which a jet of steam may be impelled. To put it in operation, the ball is, in the first instance, filled with water, and then heat applied to its external surface. As soon as the fluid boils, the steam is impelled from the mouth of the tube with great violence, and the apparatus thus constructed, forms a very good substitute for the ordinary bellows. On a larger scale, it is sometimes used to increase the draft of a steam engine furnace, as a jet of high pressure steam will carry with it a great deal of air, and when directed against the lower bars of the furnace, materially increase the effect of the fire.



In the above wood-cut a machine is represented employed by the editor in his public lectures, in which the æolipile is made to revolve. It consists of a circular tube formed into one continuous ring, and supported by a pointed steel axis. Two small bent tubes are seen to rise from the upper part of the ring, and when fire is applied beneath, the steam rushes from the apertures, and acting like the common rocket wheel, produces a continuous rotatory motion.

A beautiful modification of the revolving æolipile may now be adverted to. It is shown in the above figure, and is intended to illustrate the principle on which Hero of Alexandria is said to have constructed a steam engine, giving motion to small automata. In the latter case, the fire was applied above, and the air expanded, or spirituous vapour formed by the heat. A small tube, passing through the centre of the temple, was furnished with tubes and horizontal apertures, as in the former instance; and as the figures were attached to the thin plate beneath, their rotatory motion was the result.

ÆRIFORM, a term used to denote bodies which are airlike or gaseous. See *Gas*.

ÆROLITHS, or meteoric stones, the name given to those mineral substances which occasionally fall through the atmosphere to the earth. The concordance of a multitude of facts seems to render it indisputable, that certain stony and metallic bodies have

at various periods fallen to the earth; but the rarity of this phenomenon was for a great length of time a powerful obstacle to belief in the minds of the learned. It was long believed that they presented one of the forms assumed by thunder in its descent, and they were then considered as the products of the explosion of certain luminous balls which are sometimes observed during a thunder-storm. The first of these peculiar substances, which seems to have been examined with any degree of minuteness, was the stone presented, in 1768, to the Academie Royale des Sciences, by M. l'Abbé Bachelay, and which, when found, was still hot. The academicians analysed it, and were induced to conclude that it did not fall from the heavens, and that it was nothing but a species of pyrites which had lain covered by a thin stratum of earth until struck by the lightning and exposed to view. The attention of the philosophers of this country was first called to this subject by the fall of one of these masses, weighing 55 lbs., which occurred in 1795, near Wold Cottage, in Yorkshire; and a similar and more striking phenomenon happening three years afterwards at Benares in the East Indies, it began to excite the greatest interest. During the public exhibition of the former, which succeeded its discovery, Sir Joseph Banks observed a resemblance between it and a substance of a similar nature, which he had received as one of the stones which fell at Sienna, about eighteen hours after the celebrated eruption of Vesuvius, in 1794. He immediately procured a specimen, and submitted it for analysis, together with a portion of his Italian stone, to an able chemist, Mr. Edward Howard. This gentleman subsequently obtained specimens of the Benares stone, and also of one in the cabinet of the right honourable Charles Greville, which fell in 1753, at Plann, in Bohemia; both of which, together with the others, underwent a most minute examination. They all appeared to have the same character, and to be intimately related; their surfaces were of a dark colour, and consisted of a semivitrified and blistered crust; and when broken, they exhibited an ash-grey stony appearance, intermixed with spangles of pyrites and of native iron. They seemed to be composed principally of substances of four kinds, independently of their external coating of oxide of iron; the first being in the form of dark grains, consisting of silica, magnesia, iron, and nickel; the second, of a species of pyrites, composed of sulphur, iron, nickel, and a portion of extraneous earthy matter; the third, of metallic iron, and the fourth of a grey earthy material, which served as a cement to the others, and which consisted of the same materials in almost the same proportions as the first substance. The proportions of these bodies varied in the different specimens, the iron abounding most in those which were obtained from Yorkshire and Benares. The examinations of Mr. Howard were afterwards repeated and verified by Vauquelin and Klaproth.

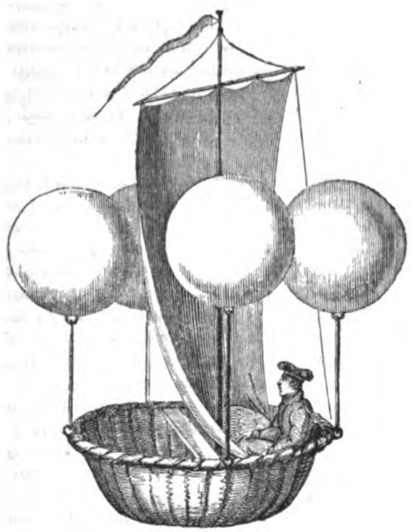
A considerable analogy exists between what is termed native iron and the substances we have just described; it is in many cases combined with another metal, nickel, which is always an ingredient in those masses called meteoric stones, which have been actually seen falling in the air. Hence a similar origin has been assigned to both; and Pallas describes a block of this iron found on the top of a mountain in Siberia, which the Tartars considered as a sacred relic which had dropped from heaven. There is now in the Imperial Museum of Vienna a large mass of aerial iron, which was actually seen to fall through the atmosphere in a state of incandescence; this occurred in Croatia, in 1751. Mr. Howard examined specimens of several masses of native iron, and from the results of his experiments, in which he coincided with Proust, he seems to think it not impossible that their origin may be the same with that of meteoric stones.

Although philosophers have devoted much of their attention to the investigation of the nature and origin of these bodies, yet we are at the present moment as ignorant of the part of space in which they are formed, and of the manner of their formation, as we were at the very commencement of the inquiry. As there were no analogous phenomena which could indicate the formation of hard metallic substances within the limits of our own atmosphere, it was natural to seek for their origin in the nearest of the planets; and hence it has been very generally maintained by many distinguished individuals that meteoric stones have their origin in the moon, and that they are by some powerful volcanic agency projected to such a height from her surface as to be more strongly attracted by the earth than by that planet, and consequently to be compelled to continue their course until they arrive at the confines of our atmosphere, and are retarded in their velocity by its resistance. This hypothesis was supported in France by Laplace, and the inflammation and combustion of the stones was attributed to the intense heat which must necessarily be evolved by the great compression of the air which would be produced by the velocity with which these bodies must enter the atmosphere. M. Biot has calculated that an initial velocity, about five times as great as that which a cannon ball sometimes receives, would be sufficient for the projection of a body from a lunar volcano into the limit of the earth's superior attraction, which is situated at nearly one-ninth of the distance of the earth from the moon.

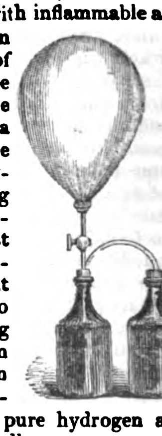
The improbability of the existence of such a high degree of volcanic force in so small a planet as the moon, has led to other speculations, and it has been maintained by some that ærolīths are portions of small invisible planets circulating round the earth; by others, that they are the fragments of a large planet which formerly existed between Mars and Jupiter, and of which the four small planets, Ceres, Pallas, Juno, and Vesta, are the remaining fragments; and lastly, that they are minerals in their primitive state, which have been ejected from the interior of our own globe by volcanoes situated in the polar regions, which produce at the same time the phenomena of the northern lights. The last of these opinions is that of M. de Lagrange, who however coincides in all his views with Dr. Brewster, who previously proposed the hypothesis which derives the origin of these substances from a formerly existing planet. Lagrange supposes the bursting of a planet to be a very probable event; and he has investigated formulæ for computing the velocity with which the fragments of a burst planet must be projected in order to move in elliptical parabolic, or hyperbolic orbits. Assuming the initial velocity of a cannon ball at 1400 French feet per second, he has shown that in the case of a planet situated beyond the orbit of Uranus, a velocity twelve or fifteen times greater than that of a cannon ball would be sufficient to make the fragments move in an ellip-

tical or parabolic orbit, whatever be their dimensions and the directions in which they are projected. A variety of circumstances concur to prove, with an evidence amounting almost to demonstration, that the four small planets, of late years, discovered between the orbits of Mars and Jupiter, are fragments of a large celestial body which once existed, and which may be supposed to have been burst in pieces by an internal force capable of overcoming the mutual attraction of the fragments. When this great convulsion took place, a number of little fragments, detached together with the greater masses, would on account of their smallness be projected with very great velocity; and being thrown beyond the attraction of the larger portions, might fall towards the Earth when Mars happened to be in the remote part of his orbit. They might then revolve about that body at different distances, and might fall upon its surface in consequence of a diminution of their centrifugal force; or, being struck by the electric fluid, they might be precipitated on the Earth, and exhibit all the phenomena which usually accompany the descent of meteoric stones.

Aeronautics; the art of sailing in or navigating the air. The idea of inventing a machine, which should enable us to rise into the air, appears to have occupied the human mind even in ancient times, but was never realized till the last century. The first suggestion for a sailing vessel with any pretensions to the character of science, is due to Francis Lana, a distinguished jesuit. This occurred in 1670; and the arrangement of the apparatus will be best understood by referring to the following figure.



Lana, it will be seen, proposed to support his car by the aid of four balls. These were to be exhausted of air; and the inventor argued that their diminished weight would cause the balls to support themselves and the aëronaut. We notice this apparatus, as similar schemes have been put forth even within our own times; but it must be obvious to any intelligent mind, that the external pressure of the atmosphere would destroy the vessels, even if they could be rendered light enough. Henry Cavendish, having discovered, about 1766, the great levity of inflammable air or hydrogen gas, Dr. Black, of Edinburgh, was led to the idea that a thin bladder, filled with this gas, must ascend into the air. Cavallo made the requisite experiments in 1782, and found that a bladder was too heavy, and paper not air tight. Soap bubbles, on the contrary, which he filled with inflammable air, rose to the ceiling of the room where they burst.—In the same year, the brothers Stephen and Joseph Montgolfier constructed a machine which ascended by its own power. In Nov. 1782, the elder Montgolfier succeeded, at Avignon, in causing a large bag of fine silk, in the shape of a parallelopiped, and containing 40 cubic feet, to mount rapidly upwards to the ceiling of a chamber, and afterwards, in a garden, to the height of 36 feet, by heating it in the inside with burning paper. The two brothers soon afterwards repeated the experiment at Annonay, where the parallelopiped ascended in the open air 70 feet. A larger machine, containing 650 cubic feet, rose with equal success.—They now resolved to make the experiment on a large scale, and prepared a machine of linen, lined with paper, which was 117 feet in circumference, weighed 430 pounds, and carried more than 400 pounds of ballast. This they sent up, June 5, 1783, at Annonay. It rose in tėn minutes to a height of 6,000 feet, and fell 7,668 feet from the place of ascension. The method used to cause it to ascend was, to kindle a straw fire under the aperture of the machine, in which they threw, from time to time, chopped wood. But, though the desired effect was produced, they had no clear nor correct idea of the cause. They did not attribute the ascension of the vessel to the rarefaction of the air enclosed in it by the operation of the heat, but to a peculiar gas, which they supposed to be developed by the burning of the straw and wood. The error of this opinion was not discovered till a later period.—These experiments roused the attention of all the philosophers of Paris. It occurred to some of them, that the same effect might be produced by inflammable air. M. Charles, professor of natural philosophy, filled a ball of lutestring, 12 feet in diameter, and coated with a varnish of gum-elastic, with such gas. It weighed 25 pounds, rose 3,123 feet in two minutes, disappeared in the clouds, and descended to the earth, after three-quarters of an hour, at the village of Gonesse, about 15 miles from Paris. Thus we see two original kinds of balloons; those filled with heated air, and those filled with inflammable air.



The process of filling balloons on the small scale for this species of aërial navigation, will readily be understood by a reference to the accompanying sketch, in which a simple condenser is employed. The common mode is to generate hydrogen gas in a bottle, by pouring dilute sulphuric acid on granulated zinc, but the hot and moist vapour from the acid speedily destroys the balloon. To prevent this, the experimentor has only to employ a second bottle containing water, and carry a bentpipe from the first bottle through a cork in the second, it dips beneath the surface, and is condensed, and the pure hydrogen ascends by the second pipe to the balloon.

To continue, Montgolfier had gone to Paris, and found an assistant in Pilater de Rozier, the superintendent of the Royal Museum. They completed together, in Oct. 1783, a new machine, 74 feet in height,

and 48 in breadth, in which Rozier ventured for the first time to ascend, though only 50 feet. The balloon was from caution fastened by cords, and soon drawn down. Eventually the machine, being suffered to move freely, took an oblique course, and at length sunk down gradually about 100 feet from its starting place.—By this the world was convinced that a balloon might, with proper management, carry a man through the air; and the first aërial expedition was determined on.

Nov. 21, 1783, Pilatre de Rozier and the marquis d'Arlandes ascended from the castle la Muette, in the presence of an innumerable multitude, with a machine containing 6,000 cubic feet. The balloon, after having attained a considerable height, came down, in 25 minutes, about 9,000 yards from la Muette. But the daring aeronauts had been exposed to considerable danger. The balloon was agitated very violently several times; the fire had burnt holes in it; the place on which they stood was injured, and some cords broken. They perceived that it was necessary to descend without delay; but when they were on the surface of the earth, new difficulties presented themselves. The weak coal fire no longer supported the linen balloon, the whole of which fell into the flame. Rozier, who had not yet succeeded in descending, just escaped being burnt.—M. Charles, who had joined with M. Robert, soon after informed the public that they would ascend in a balloon filled with inflammable air. To defray the necessary expense of 10,000 livres, he opened a subscription. The balloon was spherical, 26 feet in diameter, and consisted of silk coated with a varnish of gum-elastic. The car for the aëronauts was attached to several cords, which were fastened to a net, drawn over the upper part of the balloon. A valve was constructed above, which could be opened from the car, by means of cords, and shut by a spring. This served to afford an outlet to the inflammable air, if they wished to descend, or found it necessary to diminish it. The filling lasted several days; and, Dec. 1, the voyage was commenced from the gardens of the Tuilleries. The balloon quickly rose to a height of 1800 feet, and disappeared from the eyes of the spectators. The aëronauts diligently observed the barometer, which never stood at less than 26°, threw out gradually the ballast they had taken in to keep the balloon steady, and descended safely at Nesle. But as soon as Robert stepped out, and it was thus lightened of 130 pounds, it rose again with great rapidity about 9,000 feet. It expanded itself with such force, that it must have been torn to pieces, had not Charles, with much presence of mind opened the valve to accommodate the quantity of gas to the rarity of the surrounding atmosphere. After the lapse of half an hour, the balloon sunk down on a plain, about three miles from the place of its second ascent.

Another ascent, which nearly proved disastrous to the aeronauts, may now be noticed.—On the 15th of July, 1784, the Duke of Chartres, the two brothers Roberts, and another person, ascended with an inflammable-air balloon from the park of St. Cloud, at 52 minutes past 7 o'clock in the afternoon. This balloon was of an oblong form, measuring 55½ feet in length, and 34 in diameter. It ascended with its greatest extension nearly horizontal; and after remaining in the atmosphere about 45 minutes, it descended at a little distance from whence it had ascended, and at about 30 feet distance from the *Lac de la Garenne*, in the park of *Meudon*. But the incidents that happened in this aerial excursion deserve to be particularly described, as nothing like it had happened before to any of the aerial travellers. This machine contained an interior smaller balloon filled with common air; by which means, according to a mode hereafter to be mentioned, the machine was to be made to ascend or descend without any loss of inflammable air or ballast. The boat was furnished with a helm and oars, intended to guide it, &c.

On the level of the sea the barometer stood at 30.25 inches, and at the place of departure it stood at 30.12. Three minutes after its ascending, the balloon was lost in the clouds, and the aërial voyagers lost sight of the earth, being involved in a dense vapour. Here an unusual agitation of the air, somewhat like a whirlwind, in a moment turned the machine three times from the right to the left. The violent shocks which they suffered, prevented their using any of the means prepared for the direction of the balloon, and they even tore away the silk stuff of which the helm was made. Never, said they, had a more dreadful scene presented itself to any eye, than that in which they were involved. An unbounded ocean of shapeless clouds rolled one upon another beneath, and seemed to forbid their return to the earth, which was still invisible. The agitation of the balloon became greater every moment. They cut the cords which held the interior balloon, which consequently fell on the bottom of the external one, just upon the aperture of the tube, which went down into the boat, and stopped it up. At this time the thermometer shewed a little above 44°. A gust of wind from below drove the balloon upwards, to the extremity of the vapour, when the appearance of the sun showed them the existence of nature; but now both the heat of the the sun, and the diminished density of the atmosphere, occasioned such a dilation of the inflammable air, that the bursting of the balloon was apprehended; to avoid which they introduced a stick through the tube that proceeded from the balloon, and endeavoured to remove from its aperture the inner balloon, which closed it; but the dilatation of the inflammable air pushed the inner balloon so violently against the aperture of the tube, that every endeavour proved ineffectual. During this time, they still continued to ascend, until the mercury in the barometer stood not higher than 24.36 inches, which shows their height above the surface of the earth to be about 5,100 feet. In these dreadful circumstances, they thought it necessary to make a hole in the balloon, in order to give an exit to the inflammable air; and the Duke of Chartres, by means of one of the banners, made two incisions, which caused a rent of between seven and eight feet. They then descended very rapidly, seeing at first no object on earth or in the heavens; but a moment after they discovered the fields, and were descending straight towards a lake, into which they must have fallen, had they not thrown overboard about sixty pounds weight of ballast, which occasioned their coming down at about thirty feet beyond the edge of the lake. Notwithstanding this rapid descent, occasioned by the great quantity of gas which escaped out of the two rents in the balloon, none of the four adventurers was hurt; but spoke in the highest terms of excitement of the pleasures of their expedition.

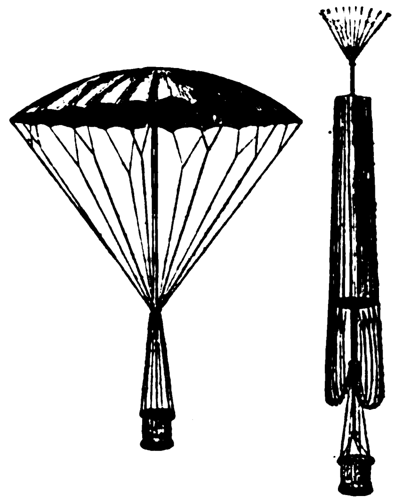
These successful aerial voyages were soon followed by others. Blanchard had already ascended several

times, when he determined to cross the channel between England and France, which is about 23 miles wide, in a balloon filled with inflammable air. He succeeded in this bold attempt, Jan. 7, 1785, accompanied by an American gentleman, Dr. Jeffries. About one o'clock they left the English coast, and at half-past two, were on the French. Pilatre de Rozier, mentioned before as the first aeronaut, attempted, June 14, 1785, in company with Mr. Romain, to pass from the French to the English side; but the attempt was unsuccessful, and the adventurers lost their lives. M. de Rozier had on this occasion united the two kinds of balloons; under one, filled with inflammable air, which did not alone possess sufficient elevating power, was a second, filled by means of a coal fire under it. Rozier had chosen this combination, hoping to unite the advantages of both kinds. By means of the lower balloon, he intended to rise and sink at pleasure, which is not possible with inflammable air; for a balloon filled with this, when once sunk to the earth, cannot rise again with the same weight, without being filled anew; while, on the contrary, by increasing or diminishing the fire under a balloon filled with heated air, it can be made to rise and fall alternately. But this experiment caused the death of the projectors. Probably the coals, which were only in a glowing state near the surface of the ground, were suddenly kindled to a light flame as the balloon rose, and set it on fire. The whole machine was soon in flames, and the two aeronauts were precipitated from the air. The condition of their mangled bodies confirms the conjecture that they were killed by the explosion of the gas.—This unhappy accident did not deter others; on the contrary, the experiments were by degrees repeated in other countries.

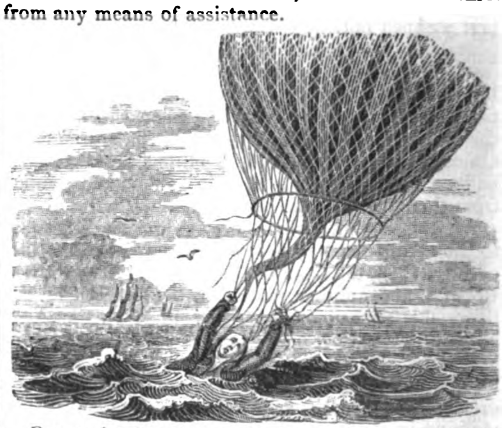
However important this invention may be, it has as yet led to no considerable results. Its use has hitherto been confined to observations in the upper regions of the atmosphere. But should we ever learn to guide the balloon at will, it might, perhaps, be employed for purposes of which we now have hardly an idea; possibly the plan of professor Robison might be accomplished by the construction of a gigantic balloon, which would enable us to perform an aerial circumnavigation of the earth. During the French revolution, an aerostatic institution was founded at Meudon, not far from Paris, for the education of a corps of aeronauts, with the view of introducing balloons into armies as a means of reconnoitring the enemy. But this use of balloons was soon laid aside, for, like every other, it must be attended with great uncertainty, as long as the machine has to obey the wind. Among the French, Blanchard and Garnerin have undertaken the greatest number of aerial voyages; among the Germans, professor Jungius, in Berlin, in 1805 and 1806, made the first. Since that time, professor Reichard and his wife have become known by their aerial excursions. Even in Constantinople, such a voyage was performed, at the wish and expense of the sultan, by two Englishmen, Barly and Devigne. Blanchard has rendered an essential service to aeronauts by the invention of the parachute, which they can use, in case of necessity, to let themselves down without danger.

The arrangement of the parachute, with reference to its use for aeronautic purposes, may now be more fully illustrated.

In the right hand figure, M. Garnerin's apparatus is seen as it ascended from St. George's parade. A cylindrical box, about three feet in height, and two in diameter, was attached by a straight pole to a truck or disc at the top, and from this was suspended a large sheet of linen somewhat similar to an umbrella. The form it assumed on the descent of the aeronaut is shown in the next figure. When first cut from the balloon, it descended with amazing velocity, and those who witnessed its progress considered the destruction of the aeronaut as certain; but after a few seconds the canvas opened, and the resistance was so great, that the apparatus diminished in its speed, till on its arrival near the earth it was not greater than would have resulted from leaping a height of two feet.



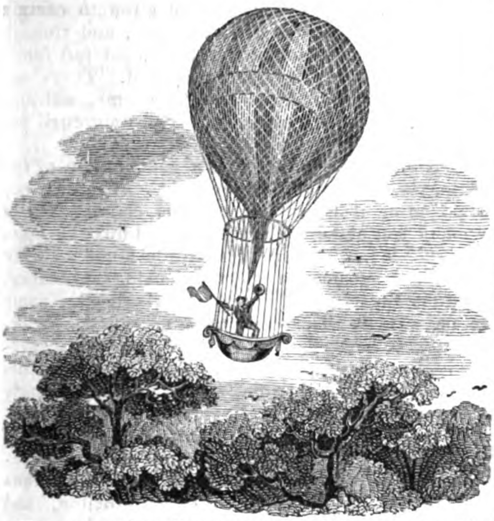
Amongst the unfortunate aeronauts we may place Major Money, who ascended from Norwich, under the full impression that the aerial current would take the balloon in the direction of Ipswich. Scarcely, however, had he attained an altitude of one mile, when a violent hurricane, operating in a new direction, drove the balloon towards Yarmouth. Several small row boats immediately put out from that port, and endeavoured to keep pace with the balloon, but without success, and Major Money first touched the sea about nine miles from land, and more than three from any means of assistance.



Our artist has delineated the situation of Major Money at the period we have now been describing, or rather about ten minutes after he had parted with

a portion of his clothes and instruments; and it was only by the assistance of a fast sailing cutter, which happened to lay in the track of the balloon, that he was saved, when almost exhausted.

Having thus given a brief account of the early history of the aerostatic art, and of the successive improvements which the balloon has undergone both in its external form and appearance, and the nature of the material used for inflation; we may now speak of the very beautiful machines which are employed for aerial excursions by the aeronauts of the present day.



The preceding illustration exhibits a very picturesque view of the ascent of that veteran, Mr. Green, from the Park, on the occasion of the coronation of his late majesty, George IV. The balloon itself, the form of which is similar to, but infinitely more beautiful than a pear, is composed of strips of variegated silk, the harmony of which has a particularly pleasing effect on the eye. Over this is thrown an envelope of net-work, which passing down serves as a support to which the car is attached.

The utility of aeronautic studies and experiments has been very much questioned even by philosophical minds. M. Cavallo, well known in the philosophical world, suggested long ago that small balloons, especially those made of paper, and raised by means of spirits of wine, may serve to explore the direction of the winds in the upper regions of the atmosphere, particularly when there is a calm below; and we see the French aëronauts adopted this idea, that they might serve also for signals in various circumstances, in which no other means can be used; and letters or other small things may be easily sent by them; for instance, from ships that cannot safely land on account of storms; from besieged places, islands, or the like. The larger aerostatic machine, he adds, may answer all the above-mentioned purposes in a better manner; and they may, besides, be used as a help to a person who wants to ascend a mountain or a precipice, or to cross a river; and perhaps one of the machines tied to a boat by a long rope, may be, in some cases, a better sort of sail than any that is used at present. Their conveying people from place to place with great swiftness, and without trouble, may be of essential use, even if the art of guiding them in a direction different from that of the wind should never be discovered. By means of those machines the shape of certain seas and lands may be better ascertained; men may ascend to the top of mountains they had never visited before; they may be carried over marshy and dangerous grounds; they may by that means come out of a besieged place, or an island; they may, in hot climates, ascend to a cold region of the atmosphere, either to refresh themselves, or to observe the ice which is never seen below; and, in short, they may be thus taken to several places, to which human art hitherto knew of no conveyance.

Ærophobia, a term that has been sometimes used for the dread of fresh air. Dr. Franklin says, that he has been sometimes seized with this ærophobia, considering fresh air as an enemy, and excluding it from the rooms which he has occupied. But experience convinced him of his error, and taught him to regard fresh air as eminently conducive to health. Any air, he says, is preferable to that of a close chamber, which has been again and again respired without any change. The same sagacious philosopher has occasionally rallied those valetudinarians, who, wrapping themselves in close garments, hurry from the noxious air of a close chamber, with as much of it as they can carry with them, into as close a carriage, from which the external air is carefully excluded, and thus proceed to take the air for the benefit of their health.

Æruginous, something partaking of, or like to, the rust of copper. Authors do not seem perfectly agreed about the colour to be expressed by this word, some expressing by it green, others brown.

Ærugo, denotes rust, especially that of copper.

Æscaldarium, or cast brass, otherwise called æsolarium, or pot brass, is a species of brass mentioned by Pliny, which was not capable of being hammered. This is likewise a term used by the German mineralists, for a substance which sometimes occurs to those who work upon cobalt, and is used for making the fine blue colour called smalt.

Æs Corinthium, a precious metallic composition, of a much finer colour than common brass, and from its beauty, little inferior to gold. Pliny says (Hist. tom. ii. p. 640. Ed. Hard.), that this was an accidental mixture of metals at the sack and conflagration of Corinth by L. Mummius, 146 years before Christ; when the gold, silver, and brass statues, and all metallic substances, melting and mingling together, formed this mass. He says, that there were three sorts of Corinthian brass, viz. the red, the white, and that which was of the colour of money, according to the different proportions of gold and silver that were in it. But some refiners, who have strictly examined this metal, find no gold in it; a circumstance which, if true, suggests one reason, among others, for concluding, that this account is fabulous. However, the fable has been interpreted by some to signify, that the art of making copper into brass was first discovered by the Corinthians, who found the calamine stone on the plains of Peloponesus, or, at least, that they brought this art to perfection.

Æs Grave denoted money among the Romans, which was paid by weight, and not by tale. In this sense it is used by Buddæus and Scaliger.

But others, by æs grave, understand large pieces of copper coined, containing, for instance, an as, or

pound of that metal, such as we find current in Sweden. These, they assert, bore the title æs grave, till the time in which they were reduced to a smaller standard. Gronovius, on the contrary, maintains, that the as, or pound weight, did not acquire the appellation, æs grave, till after their reduction. (*Philos. Trans.* No. 19.) Kuster rejects all these opinions, and asserts, that the expression is used to denote any kind of copper money compared with gold or silver; which, with regard to the bulk, and size of the pieces, was much lighter, though of greater value.

But this system, however plausible, is rejected by several learned men, particularly Perizonius and Mr. Ward. The former has a dissertation on the subject, in which the opinion of Gronovius is farther examined and defended.

Æs Ustum, called also Æs Veneris,—Æs Cremantum,—Crocus Veneris, and Cinis Æris,—is a term which, like many others among the old chemists, has been applied to two or three different substances; it is, therefore, on this account deservedly rejected from the reformed nomenclature. Hunkel (*Labor. Chem.* p. iii. c. 39) employs it as a general denomination for a perfect oxide of copper prepared by heat; the expression is, however, more commonly employed to denote a pharmaceutical preparation once much in vogue as an escharotic, but now fallen into disuse. This æs ustum essentially consists of copper and sulphur; and the different varieties originate from the relative proportions of the ingredients, and the different states of oxidation of the copper. It is usually prepared by stratifying in a crucible copper clippings and powdered sulphur, and heating the crucible by degrees, till it ceases to emit any vapours; it must then be raised to a dull red heat for an hour; there results a brittle mass, which, when pulverized and washed, is the substance in question.

Barchusen's method is still more simple, consisting merely in heating a slip of copper to whiteness, and rubbing it with a roll of brimstone; as soon as it is taken out of the fire, the copper combines eagerly with the sulphur, and the compound runs down in drops, and is received in a basin of water: this is then pulverized and washed. In both these cases the compound is a slightly oxydated copper, saturated with sulphur; of an iron brown colour. In addition to this process, Lemery goes on to heat the sulphurated oxide in a reverberatory nine times successively, quenching it in linseed oil after each roasting. He thus obtains a product of a high red colour, which, in fact, is a simple oxide of copper, the sulphur being burnt out. Some recommend a mixture of nitre or common salt with the sulphur, and the substance resulting from this, if not washed, is certainly a very powerful escharotic, on account of the sulphurated alkali which is thus combined with the oxide of copper. As to the sal ammoniac and vinegar, in which some previously steep the copper, it is wholly useless, all its effect being destroyed by the subsequent heating. *Dict. Method. Art.* Æs Ustum.

Æsculapius, in *Astronomy*, the ancient name for the constellation Ophincus.

Æther; an extremely fine, subtile, and elastic fluid, which philosophers have supposed to be diffused throughout the universe, and by means of which they have explained many of the great phenomena of nature. It is mentioned by Aristotle. Its existence cannot be proved. Newton believed in it, and explains by it the connexion of the parts of a body, and the laws of gravity. Euler asserts that æther is almost 39,000,000 times thinner, and 1,278 times more elastic, than atmospheric air.

Æther; in *Chemistry*, see Ether.

Ætherial Oil is a fine, subtile, essential oil, approaching nearly to the nature of a spirit. Thus, the pure liquor rising next after the spirit, in the distillation of turpentine, is called the ætherial oil of turpentine.

Ætherial Phosphorus, is a name generally given by Bernoulli, to that otherwise called mercurial, or borometrical phosphorus.

Æthiops, in *Pharmacy*, a name given to certain metallic preparations of a dark colour; and though the term is at present superseded, it is yet too familiar to chemists to be wholly omitted. There are four pharmaceutical articles of this name, æthiops antimonialis, æthiops martialis, æthiops murcurii per se, and æthiops mineralis.

Æthiops Antimonialis, is a combination of the sulphurets of antimony and mercury. The old way of preparing it is, to mix together equal parts of common salt and crude antimony, and flux the mass in a crucible; when cold, there will be found a dusky scoria, resting upon a metallic-looking substance, which is the crude antimony, nearly in the same state as at first. The scoria being separated, the antimony is to be ground with an equal weight of mercury, till they are well united. The first part of this process seems wholly unnecessary, and accordingly the antimonial æthiops is generally made by trituration of crude antimony with an equal weight of mercury. A still more expeditious, and equally efficacious, way of preparing this mixture is, to fuse some crude antimony in an earthenware crucible, and when it is upon the point of fixing, to add to it an equal weight of hot mercury; the mixture immediately becomes more fluid, and after awhile becomes solid: when cold, it must be levigated in a mortar, and washed.

Affinity, in *Chemistry*. When two bodies are brought in contact with each other, they will often, without the sensible operation of any extraneous influences, combine by a spontaneous and reciprocal action, and form new bodies with different properties; a single body, modified by the action of the natural agents, caloric, electricity, &c., sometimes produces the same results; finally, a body not apparently acted upon by other bodies, nor by the natural agents, sometimes acquires new properties, and assumes new forms. These changes in the chemical character of bodies are produced by a force, to which we give the name of *affinity*. Some of the laws or modes of action of this force are, that it is exerted only at insensible distances, which distinguishes it from *gravitation* (see *Attraction*), and between heterogeneous particles, in which it differs from *cohesion*. The properties of the resulting compound differ essentially from its component parts, as a salt is formed by an acid and an alkali. The forms of the elements are often changed, and the change is attended with remarkable phenomena, as the explosion of gunpowder by its conversion into gases, the solidification of water in slaking lime, &c. One of the most important laws of affinity is, that one body has not the same force of affinity towards all others, but attracts them very unequally, and some of them not at all. The knowledge of the affinities of different bodies is of great use to the chemist in effect-

ing decompositions. Bergmann, who first, in 1775, developed the theory of affinities, distinguishes three cases in the reciprocal action of two bodies—when they are both free, which he calls *simple affinity;* when one of them is already in combination, *elective;* and when both are combined in different compounds, *complex*. Berthollet has much improved the theory of affinities. (See *Atomic Theory;* also *Berthollet's Statique Chimique;* and *Berzelius' Theory of Chemical Proportions.*)

Agio is the difference in value between bank money and coin, or other currency. The term is in most frequent use in Holland and Venice. It is, however, used at Hamburg and other places in Germany. It is synonymous with *premium*, when the bank money is worth more than the same nominal amount of the current coin, and with *discount*, when its value is less. The agio at the bank of Amsterdam was from three to four per cent. before the French invasion of Holland in 1795; that of Venice was formally fixed at 20 per cent.; the bank money of each of those places being so much more valuable than the current coin. This difference in value arises often from the circumstance, that the current coin is depreciated by wearing and clipping. The agio of the bank money of Hamburgh was formerly 14 per cent. on this account. Agio is sometimes used to signify the premium or discount on bills of exchange.

Aggregation, in *Physics;* a species of union, whereby several things, which have no natural dependence or connexion with one another, are collected together, so as, in some sense, to constitute one. Thus, a heap of sand, or a mass of ruins, are bodies by aggregation.

Agriculture is the art of cultivating the earth in such a manner as to cause it to produce, in the greatest plenty and perfection, those vegetables which are useful to man, and to the animals which he has subjected to his dominion. This art is the basis of all other arts, and in all countries coeval with the first dawn of civilization. Without agriculture, mankind would be savages, thinly scattered through interminable forests, with no other habitations than caverns, hollow trees or huts, more rude and inconvenient than the most ordinary hovel or cattle-shed of the modern cultivator. It is the most universal as well as the most ancient of the arts, and requires the greatest number of operators. It employs seven-eighths of the population of almost every civilized community.—Agriculture is not only indispensable to national prosperity, but is eminently conducive to the welfare of those who are engaged in it. It gives health to the body, energy to the mind, is favourable to virtuous and temperate habits, and to knowledge and purity of moral character, which are the pillars of good government and the true support of national independence.—With regard to the history of agriculture, we must confine ourselves to slight sketches. The first mention of agriculture is found in the writings of Moses. From them we learn that Cain was a "tiller of the ground," that Abel sacrificed the "firstlings of his flock," and that Noah "began to be a husbandman, and planted a vineyard."

The Chinese, Japanese, Chaldeans, Egyptians, and Phœnicians appear to have held husbandry in high estimation. The Egyptians were so sensible of its blessings, that they ascribed its invention to superhuman agency, and even carried their gratitude to such an absurd excess as to worship the ox, for his services as a labourer. The Carthaginians carried the art of agriculture to a higher degree than other nations, their contemporaries. Mago, one of their most famous generals, wrote no less than twenty-eight books on agricultural topics, which, according to Columella, were translated into Latin by an express decree of the Roman senate.

Hesiod, a Greek writer, supposed to be a contemporary with Homer, wrote a poem on agriculture, entitled *Weeks and Days*, which was so denominated because husbandry requires an exact observance of times and seasons. Other Greek writers wrote on rural economy, and Xenophon among the number, but their works have been lost in the lapse of ages. The implements of Grecian agriculture were very few and simple. Hesiod mentions a plough, consisting of three parts—the share-beam, the draught-pole, and the plough-tail; but antiquarians are not agreed as to its exact form; also a cart with low wheels, and ten spans (seven feet six inches) in width; likewise the rake, sickle, and ox-goad; but no description is given of the mode in which they were constructed. The operations of Grecian culture, according to Hesiod, were neither numerous nor complicated. The ground received three ploughings—one in autumn, another in spring, and a third immediately before sowing the seed. Manures were applied, and Pliny ascribes their invention to the Grecian king Augeas.

Theophrastus mentions six different species of manures, and adds, that a mixture of soil produces the same effect as manures. Clay, he observes, should be mixed with sand, and sand with clay. Seed was sown by hand, and covered with a rake. Grain was reaped with a sickle, bound in sheaves, threshed, then winnowed by wind, laid in chests, bins or granaries, and taken out as wanted by the family, to be pounded in mortars or quern mills into meal.—The ancient Romans venerated the plough, and, in the earliest and purest times of the republic, the greatest praise which could be given to an illustrious character was to say that he was an industrious and judicious husbandman. M. Cato, the censor, who was celebrated as a statesman, orator, and general, having conquered nations and governed provinces, derived his highest and most durable honours from having written a voluminous work on agriculture.

In the Georgics of Virgil, the majesty of verse and the harmony of numbers add dignity and grace to the most useful of all topics. The celebrated Columella flourished in the reign of the emperor Claudius, and wrote twelve books on husbandry, which constituted a complete treatise on rural affairs.

Varro, Pliny, and Palladius were likewise among the distinguished Romans who wrote on agricultural subjects. With regard to the Roman implements of agriculture, we learn that they used a great many, but their particular forms and uses are very imperfectly described. From what we can ascertain respecting them, they appear more worthy of the notice of the curious antiquarian, than of the practical cultivator. The plough is represented by Cato as of two kinds—one for strong, the other for light soils. Varro mentions one with two mould-boards, with which, he says, "when they plough, after sowing the seed, they are said to ridge." Pliny mentions a plough with one mould-board, and others with a coulter, of which he says there were many kinds.—Fallowing was a practice rarely deviated

from by the Romans. In most cases, a fallow and a year's crop succeeded each other. Manure was collected from nearly or quite as many sources as have been resorted to by the moderns. Pigeons' dung was esteemed of the greatest value, and, next to that, a mixture of night soil, scrapings of the streets and urine, which were applied to the roots of the vine and olive. The Romans did not bind their corn into sheaves. When cut, it was sent directly to the area to be threshed, and was separated from the chaff by throwing it from one part of the floor to the other. Feeding down grain, when too luxuriant, was practised. Virgil says, "What commendation shall I give to him, who, lest his corn should lodge, pastures it, while young, as soon as the blade equals the furrow!" Watering on a large scale was applied both to arable and grass lands. Virgil advises to 'bring down the waters of a river upon the sown corn, and, when the field is parched and the plants drying, convey it from the brow of a hill in channels." (*Geor.* l. i, l. 106.)—The farm management most approved of by the scientific husbandmen of Rome was, in general, such as would meet the approbation of modern cultivators. The importance of thorough tillage is illustrated by the following apologue: A vine-dresser had two daughters and a vineyard; when his oldest daughter was married, he gave her a third of his vineyard for a portion, notwithstanding which he had the same quantity of fruit as formerly. When his youngest daughter was married, he gave her half of what remained; still the produce of his vineyard was undiminished. This result was the consequence of his bestowing as much labour on the third part left after his daughters had received their portions, as he had been accustomed to give to the whole vineyard.

The Romans, unlike many conquerors, instead of desolating, improved the countries which they subdued. They seldom or never burned or laid waste conquered countries, but laboured to civilize the inhabitants, and introduce the arts necessary for promoting their comfort and happiness. To facilitate communications from one district or town to another, seems to have been a primary object with them, and their works of this kind are still discernible in numerous places. By employing their troops in this way, when not engaged in active service, their commanders seem to have had greatly the advantage over our modern generals. The Roman soldiers, instead of loitering in camps, or rioting in towns, enervating their strength, and corrupting their morals, were kept regularly at work, on objects highly beneficial to the interests of those whom they subjugated. In the ages of anarchy and barbarism which succeeded the fall of the Roman empire, agriculture was almost wholly abandoned. Pasturage was preferred to tillage, because of the facility with which sheep, oxen, &c. can be driven away or concealed on the approach of an enemy.

The conquest of England by the Normans contributed to the improvement of agriculture in Great Britain. Owing to that event, many thousands of husbandmen, from the fertile and well-cultivated plains of Flanders and Normandy, settled in Great Britain, obtained farms, and employed the same methods in cultivating them, which they had been accustomed to use in their native countries. Some of the Norman barons were great improvers of their lands, and were celebrated in history for their skill in agriculture. The Norman clergy, and especially the monks, did still more in this way than the nobility. The monks of every monastery retained such of their lands as they could most conveniently take charge of, and these they cultivated with great care under their own inspection, and frequently with their own hands. The famous Thomas à Becket, after he was archbishop of Canterbury, used to go out into the field with the monks of the monastery where he happened to reside, and join with them in reaping their corn and making their hay.

The implements of agriculture, at this period, were similar to those in most common use in modern times. The various operations of husbandry, such as manuring, ploughing, sowing, harrowing, reaping, threshing, winnowing, &c., are incidentally mentioned by the writers of those days, but it is impossible to collect from them a definite account of the manner in which those operations were performed. The first English treatise on husbandry was published in the reign of Henry VIII. by Sir A. Fitzherbert, judge of the common pleas. It is entitled the *Book of Husbandry*, and contains directions for draining, clearing, and enclosing a farm, for enriching the soil, and rendering it fit for tillage. Lime, marl, and fallowing, are strongly recommended. "The author of the Book of Husbandry," says Mr. Loudon, "writes from his own experience of more than forty years; and, if we except his biblical allusions, and some vestiges of the superstition of the Roman writers about the influence of the moon, there is very little of his work which should be omitted, and not a great deal that need be added, in so far as respects the culture of corn, in a manual of husbandry adapted to the present time."

Agriculture attained some eminence during the reign of Elizabeth. The principal writers of that period were Tusser, Googe, and Sir Hugh Platt. Tusser's *Five Hundred Points of Husbandry* was published in 1562, and conveys much useful instruction in metre. The treatise of Barnaby Googe, entitled *Whole Art of Husbandry*, was printed in 1558. Sir Hugh Platt's work was entitled *Jewel Houses of Art and Nature*, and was printed in 1594. In the former work, says Loudon, are many valuable hints on the progress of husbandry in the early part of the reign of Elizabeth. Among other curious things, he asserts that the Spanish or Merino sheep was originally derived from England. Several writers on agriculture appeared in England during the commonwealth, whose names, and notices of their works, may be seen in Loudon's *Encyclopædia of Agriculture*.

From the restoration down to the middle of the eighteenth century, agriculture remained almost stationary. Immediately after that period, considerable improvement in the process of culture was introduced by Jethro Tull, a gentleman of Berkshire, who began to drill wheat and other crops about the year 1701, and whose *Horsehoeing Husbandry* was published in 1731. Though this writer's theories were in some respects erroneous, yet even his errors were of service, by exciting inquiry, and calling the attention of husbandmen to important objects. His hostilily to manures, and attempting, in all cases, to substitute additional tillage in their place, were prominent defects in his system. After the time of Tull's publication, no great alteration in British agriculture took place, till Robert Bakewell and others effected some

important improvements in the breed of cattle, sheep, and swine. By skilful selection at first, and constant care afterwards to breed from the best animals. Bakewell at last obtained a variety of sheep, which, for early maturity and the property of returning a great quantity of mutton for the food which they consumed, as well as for the small proportion which the weight of the offal bears to the four quarters, were without precedent. Culley, Cline, Lord Somerville, Sir J. S. Sebright, Darwin, Hunt, Hunter, Young, &c. &c. have all contributed to the improvement of domestic animals, and have left little to be desired in that branch of rural economy.—Among other works on agriculture, of distinguished merit, may be mentioned *The Farmer's Letters, Tour in France, Annals of Agriculture, &c. &c.* by the celebrated Arthur Young; Marshall's numerous and excellent works, commencing with *Minutes of Agriculture*, published in 1787, and ending with his *Review of the Agricultural Reports* in 1816; *Practical Agriculture*, by Dr. R. W. Dickson, &c. &c.

The writings of Kaimes, Anderson, and Sinclair, exhibit a union of philosophical sagacity and patient experiment, which have produced results of great importance to the British nation and to the world. To these we shall only add the name of John Loudon, F. L. S. H. S., whose elaborate *Encyclopædia of Gardening* and *Encyclopædia of Agriculture*, have probably never been surpassed by any similar works in any language.—The establishment of a national board of agriculture was of very great service to British husbandry. Hartlib, a century before, and Lord Kaimes, in his *Gentleman Farmer*, had pointed out the utility of such an institution, but it was left to Sir John Sinclair to carry their ideas into execution. To the indefatigable exertions of that worthy and eminent man the British public are indebted for an institution, whose services cannot be too highly appreciated. "It made farmers, residing in different parts of the kingdom, acquainted with one another, and caused a rapid dissemination of knowledge amongst the whole profession. The art of agriculture was brought into fashion, old practices were amended, new ones introduced, and a degree of exertion called forth heretofore unexampled among agriculturists in this island."—We may now briefly notice the progress of agriculture in the different countries of Europe and America.

French agriculture began to flourish early in the 17th century, under Henry IV., and a work on that subject was published by Olivier de Serres. In 1761, there were 13 agricultural societies in France, and 19 auxiliary societies. Those of Paris, Amiens, and Bordeaux have distinguished themselves by their memoirs. Du Hamel and Buffon made the study of rural economy fashionable, and other writers contributed to the advancement of husbandry. M. de Trudaine introduced the Merino breed of sheep in 1776, and Count Lasteyrie has written a valuable work on sheep-husbandry. The celebrated Arthur Young made an agricultural survey of France in 1787-89. Since that time, several French and English writers have given the statistics of different districts, and the mode of cultivation there in use, and the abbé Rosier and professor Thouin have published general views of the whole kingdom. Bonaparte established many new agricultural societies and professorships, botanical and economical gardens, for the exhibition of different modes of culture, and the dissemination of plants. He also greatly enlarged and enriched that extensive institution, the National Garden, whose professor of culture, the Chevalier Thouin, is one of the most scientific agriculturists in Europe.—The lands in France are not generally enclosed and subdivided by hedges or other fences. Some fences occur near towns, but in general the whole country is open, the boundaries of estates being marked by slight ditches or ridges, with occasional stones or heaps of earth, trees in rows, or thinly scattered. Depredations from passengers on the highways are prevented by *gardes champêtres*, which are established throughout all France. Since the time of Colbert, the French have paid attention to sheep, and there are considerable flocks of Merinos owned by individuals, besides the national flocks. That of Rambouillet, established in 1786, is, or lately was, managed by M. Tessier, an eminent writer on agriculture. Sheep are generally housed, or kept in folds and little yards or enclosures.

Mr. Birkbeck considers the practice of housing or confining sheep as the cause of foot-rot, a disease very common among them in France. Where flocks remain out all night, the shepherd sleeps in a small thatched hut, or portable house, placed on wheels. He guides the flock by walking before them, and his dog guards them from wolves, which still abound in some parts of the country. In the south part of France, the ass and the mule are of frequent use in husbandry. A royal stud of Arabian horses has been kept up at Aurillac, in Limousin, for more than a century, and another has been more recently established near Nismes. Poultry is an important article in French husbandry. Mr. Birkbeck thinks that the consumption of poultry in towns may be equal to that of mutton. The breed of swine is in general bad; but fine hams are made in Bretagne from hogs reared on acorns and fatted with Indian corn. The French implements of agriculture are generally rude and unwieldy, and the operations of husbandry unskilfully performed. The vine is cultivated in France in fields and on terraced hills, in a way different from that which prevails elsewhere. It is planted in hills, like Indian corn, kept low, and managed like a plantation of raspberries. The white mulberry tree is very extensively cultivated for feeding the silk-worm. It is not placed in regular plantations, but in corners, in rows by the sides of roads, &c. The trees are raised from the seed in nurseries, and sold generally, at five years' growth, when they have strong stems. They are planted, staked, and treated as pollards. The eggs of the silk-worm are hatched in rooms heated by means of stoves to 80° of Réaumur ($72\frac{1}{2}$) Fah.) One ounce of eggs requires one hundred weight of leaves, and will produce from 7 to 9 pounds of raw silk. The hatching commences about the end of April, and with the feeding, is over in about a month. Second broods are procured in some places. The silk is wound off the cocoons in little balls by women and children. The olive, the fig, the almond, and various other fruits are also extensively cultivated in France.

Before concluding our view of the agriculture of France, it may be advisable to furnish our readers with M. Dupin's comparative estimate of the above species of labour in that country, viewed in comparison with our own. It is extracted from that excellent work, the *Companion to the Almanack*.

The 31,800,000 inhabitants which now constitute

the population of France, are equivalent to a power of 12,609,057 individuals of the male sex, at the age of full vigour. It is a position generally admitted in France, that two-thirds of the population are employed in agriculture; and that a third only is occupied in manufacturing and commercial pursuits. Hence it results that France possesses

	Effective Labourers.
A human agricultural power equivalent to that of	8,406,038
And a power of industry, manufacturing and commercial, equal to . .	4,203,019
Total	12,609,057

Were it not that the industry of man had found the means of calling extraneous force to its aid, its means would be confined to the amount of power above enumerated; but man employs other forces than his own in agricultural labours, and principally that of the horse, of the ass, of the mule, the ox, and the cow; and with the help of these, the animate agricultural force of France has increased to the following sum:—

Human race .	21,056,667	equivalent to	8,406,038	labouring men.
Horses . . .	1,600,000		11,200,000	
Oxen and cows	6,973,000		17,432,000	
Asses . . .	240,000		240,000	
		Total	37,278,038	

On making similar calculations of the agricultural force of Great Britain, and stating at 15,000,000 the number of inhabitants of England and Scotland, of whom a third only are employed in agriculture, and the other two-thirds in commerce and manufactures, we shall have

Agricultural force	2,132,446	effective working men.
Artisans of all professions .	4,264,893	

If we proceed in the same way with regard to Great Britain, as we have done with respect to France, and make a comparative calculation of the power in men, and the power in other animals engaged in agriculture, we shall find,

Human race. . .	5,000,000	equivalent to	2,132,446	effective labourers.
Horses of full growth	1,250,000		8,750,000	
Oxen, cows, &c. .	5,500,000		13,750,000	
		Total	24,632,446	
		Ireland; approximating Estimate	7,455,701	
		Total for the United Kingdom	32,088,147	

Taking the proportion of this total force of 24,632,446 to the human force applicable to agriculture, we find it to be as 12. Whence it appears that the agriculturists of England and Scotland have discovered the means of creating a force, twelve times the amount of their personal corporeal force, by the use they make of domestic animals; while the additional force, obtained through similar means by the French agriculturists, does not amount to five times their own. It is calculated that in France there are 46,000,000 hectares of land made to yield produce; so that there is an animate power equal to that of 810 labourers for the cultivation of every thousand hectares. The total number of hectares of productive land in Great Britain is 21,643,000; so that there is an animate power equal to that of 1,138 working men for every thousand hectares. The produce of the land in the respective countries, is in proportion to the power employed respectively in its cultivation.

This extract, from the pen of one of the most distinguished political economists in France, will furnish a tolerably accurate view of the comparative effects of British and foreign systems of agriculture, with reference to animate and inanimate force.

Agriculture in Germany. The earliest German writer on husbandry was Conradus Heresbachius, who lived and died in the 16th century. His work, *De Re Rustica*, was an avowed compilation from all the authors who had preceded him. No other books on agriculture, of any note, appeared previous to the 17th century. With regard to the present state of agriculture in Germany, we would remark, that the country is very extensive, and presents a great variety of soils, surface, climate, and culture. Its agricultural produce is for the most part consumed within its limits; but excellent wines are exported from Hungary and the Rhine, together with flax, hams, geese, silk, &c. The culture of the mulberry and the rearing of the silk-worm are carried on as far north as Berlin. The theoretical agriculturists are well acquainted with all the improved implements of Great Britain, and some of them have been introduced, especially in Holstein, Hanover, and Westphalia; but, generally speaking, the ploughs, waggons, &c. are unwieldy and inefficient. Fish are carefully bred and fattened in some places, especially in Prussia, and poultry is every where attended to, particularly in the neighbourhood of Vienna. The culture of forests likewise receives particular attention in that country as well as in France. The common agriculture of Germany is every where improving. Government, as well as individuals, have formed institutions for the instruction of youth in its principles. The Imperial Society of Vienna, the Georgical Institution at Presburg, and that of professor Thaer, in Prussia, may be numbered among recent institutions of this description.

Agriculture in Italy. The climate, soil, and surface of Italy are so various as to have given rise to a greater diversity of culture than is to be found in the whole of Europe besides. Corn, grass, butchers' meat, cheese, butter, rice, silk, cotton, wine, oil, and fruits of all kinds are found in perfection in this fertile country. Loudon asserts that only one-fifth of the surface of Italy is considered sterile, while only a fifth of the surface of France is considered fertile. The population of Italy is greater in proportion to its surface, than that of either France or Great Britain. Among the writers on the rural economy of Italy are, Arthur Young, in 1788, Sismondi, in 1801, and Chateauvieux, in 1812. In Lombardy the lands are generally farmed by *metayers* (from *metà*, half). The landlord pays the taxes and repairs the buildings; the tenant provides cattle, implements, and seeds, and the produce is divided. The irrigation of lands in Lombardy is a remarkable feature of Italian husbandry. All canals taken from rivers are the property of the state, and may be carried through any man's land, provided they do not pass through a garden, or within a certain distance of a mansion, on paying the value of the ground occupied. Water is not only employed for grass-lands (which, when fully watered, are mowed four and sometimes five times a year, and, in some cases, as early as March), but is conducted between the narrow ridges of corn-lands, in the hollows between drilled crops, among vines, or to flood lands, to the depth of a foot or more, which are sown with rice. Water is also used for depositing a surface of mud, in some places where it is charged with that material. The details of

watering, for these and other purposes, are given in various works, and collected in those of Professor Rhe. In general, watered lands let at one-third higher price than those not irrigated. The implements and operations of agriculture in Lombardy are both imperfect. The plough is a rude contrivance, with a handle 13 or 14 feet long. But the cattle are fed with extraordinary care; they are tied up in stalls, bled once or twice, cleaned and rubbed with oil, afterwards combed and brushed twice a day. Their food in summer is clover or other green herbage; in winter, a mixture of elm-leaves, clover-hay, and pulverized walnut-cake, over which boiling water is poured, and bran and salt added. In a short time the cattle cast their hair, grow smooth, round, and fat, and so improved as to double their value to the butcher. The tomato or love-apple (*solanum lycopersicum*), so extensively used in Italian cookery, forms an article of field-culture near Pompeii, and especially in Sicily, from whence it is sent to Naples, Rome, and several towns on the Mediterranean sea.

Agriculture of the United States of America. The territory of the United States is very extensive, and presents almost every variety of soil and climate. The agriculture of this wide-spread country embraces all the products of European cultivation, together with some (such as sugar and indigo) which are rarely made objects of tillage in any part of Europe. A full description of the agriculture of these states would require a large volume. We shall confine ourselves to such sketches as we may deem of most practical importance to those who are or intend to become cultivators of North American soil. The farms of the Eastern, Northern, and Middle States consist generally of from 50 to 200 acres, seldom rising to more than 300, and frequently falling short of 200 acres. These farms are enclosed, and divided either by stone walls, or rail fences made of timber, hedges not being common. The building first erected on a "new lot," or on a tract of land not yet cleared from its native growth of timber, is what is called a log-house. This is a hut or cabin made of round, straight logs, about a foot in diameter, lying on each other, and notched in at the corners. The intervals between the logs are filled with slips of wood, and the crevices generally stopped with mortar made of clay. The fire-place commonly consists of rough stones, so placed as to form a hearth, on which wood may be burned. Sometimes these stones are made to assume the form of a chimney, and are carried up through the roof; and sometimes a hole in the roof is the only substitute for a chimney. The roof is made of rafters, forming an acute angle at the summit of the erection, and is covered with shingles, commonly split from pine-trees, or with bark peeled from the hemlock (*pinus canadensis*).—When the occupant or "first settler" of this "new land" finds himself in "comfortable circumstances," he builds what is styled a frame-house, composed of timber held together by tenons, mortises, and pins, and boarded, shingled, and clap-boarded on the outside, and often painted white, sometimes red. Houses of this kind generally contain a dining-room and kitchen, and three or four bed-rooms on the same floor. They are rarely destitute of good cellars, which the nature of the climate renders almost indispensable. The farm-buildings consist of a barn, proportioned to the size of the farm, with stalls for horses and cows on each side, and a threshing-floor in the middle; and the more wealthy farmers add a cellar under the barn, a part of which receives the manure from the stalls, and another part serves as a store-room for roots, &c. for feeding stock. What is called a corn-barn is likewise very common, which is built exclusively for storing the ears of Indian corn. The sleepers of this building are generally set up four or five feet from the ground, on smooth stone posts or pillars, which rats, mice, or other vermin cannot ascend. With regard to the best manner of clearing forest-land from its natural growth of timber, the following observations may be of use to a "first settler." In those parts of the country where wood is of but little value, the trees are felled in one of the summer months, the earlier in the season the better, as the stumps will be less apt to sprout, and the trees will have a longer time to dry. The trees lie till the following spring, when such limbs as are not very near the ground should be cut off that they may burn the better. Fire must be put to them in the driest part of the month of May, or, if the whole of that month prove wet, it may be applied in the beginning of June. Only the bodies of the trees will remain after burning, and some of them will be burned into pieces. Those which require to be made shorter are cut in pieces nearly of a length, drawn together by oxen, piled in close heaps, and burned; such trees and logs being reserved as may be needful for fencing the *lot*. The heating of the soil so destroys the green roots, and the ashes made by the burning are so beneficial as manure to the land, that it will produce a good crop of wheat or Indian corn without ploughing, hoeing, or manuring. If new land lie in such a situation that its natural growth may turn to better account, whether for timber or fire-wood, it will be an unpardonable waste to burn the wood on the ground. But if the trees be taken off, the land must be ploughed after clearing, or it will not produce a crop of any kind.

We shall conclude with a few brief notices of some of the most prominent benefits and improvements which modern science has contributed to the art of agriculture. The husbandmen of antiquity, as well as those of the middle ages, were destitute of many advantages enjoyed by the modern cultivator. Neither the practical nor the theoretical agriculturists of those periods had any correct knowledge of geology, mineralogy, chemistry, botany, vegetable physiology, or natural philosophy; but these sciences have given the modern husbandman the command of important agents, elements and principles, of which the ancients had no idea. The precepts of their writers were conformable to their experience; but the *rationale* of the practices they prescribed they could not, and rarely attempted, to explain. Nature's most simple modes of operation were to them inexplicable, and their ignorance of causes often led to erroneous calculations with regard to effects. We are indebted to modern science for the following, among other improvements: viz. 1. A correct knowledge of the nature and properties of manures, mineral, animal, and vegetable; the best modes of applying them; and the particular crops for which particular sorts of manures are best suited. 2. The method of using all manures of animal and vegetable origin while fresh, before the sun, air, and rain, or other moisture, has robbed them of their most valuable properties. It was formerly the practice to place barn-yard manure in layers or masses for the purpose of rotting, and turn

it over frequently with the plough or spade, till the whole had become a mere *caput mortuum*, destitute of almost all its original fertilizing substances, and deteriorated in quality almost as much as it was reduced in quantity. 3. The knowledge and means of chemically analyzing soils, by which we can ascertain their constituent parts, and thus learn what substances are wanted to increase their fertility. 4. The introduction of the root-husbandry, or the raising of potatoes, turnips, mangel-wurzel, &c. extensively, by field-husbandry, for feeding cattle, by which a given quantity of land may be made to produce much more nutritive matter than if it were occupied by grain or grass crops, and the health as well as the thriving of the animals in the winter season greatly promoted. 5. Laying down lands to grass, either for pasture or mowing, with a greater variety of grasses, and with kinds adapted to a greater variety of soils; such as orchard-grass (*dactylis glomerata*), for dry land, foul meadow-grass (*agrostis stricta*), for very wet land; herds'-grass or timothy (*phleum pratense*), for stiff, clayey soils, &c. &c. 6. The substitution of fallow crops (or such crops as require cultivation and stirring of the ground while the plants are growing) in the place of naked fallows, in which the land is allowed to remain without yielding any profitable product, in order to renew its fertility. Fields may be so foul with weeds, as to require a fallow, but not what is too often understood by that term in this country. "In England, when a farmer is compelled to fallow a field, he lets the weeds grow into blossom, and then turns them down; in America, a fallow means a field where the produce is a crop of weeds running to seed, instead of a crop of grain." 7. The art of breeding the best animals and the best vegetables, by a judicious selection of individuals to propagate from. —These improvements, with others too numerous to be here specified, have rendered the agriculture of the present period very different from that of the middle ages, when it had sunk far below the degree of perfection which it had reached among the Romans.

The practice of agriculture will be found fully discussed and illustrated under the articles, Plough, Harrow, Threshing Machine, &c.

Ague, in *Medicine;* a disorder belonging to the class of intermittent fevers (*febres intermittentes*). It may be followed by serious consequences, but generally it is more troublesome than dangerous, and is sometimes even considered salutary. According to the length of the *apyrexia*, or intermission between one febrile paroxysm and another, agues are denominated *quotidians, tertians,* or *quartans;* which latter are much the more obstinate, being generally attended with a greater degree of visceral obstruction than those the attacks of which return at shorter intervals. The quartan ague is apt to terminate in dropsy. An ague paroxysm has been divided into the cold, the hot, and the sweating stages. The feeling of extreme cold, in the first stage, cannot be prevented by fire or the heat of summer. Generally after the sweating stage, in which there is a profuse exhalation from the pores of the skin, with a flow of urine depositing a copious sediment of a lateritious or brick-dust appearance, the patient falls into a refreshing sleep, from which he awakes without any remains of indisposition, except a slight degree of languor and debility. Agues occur chiefly in situations where there are shallow stagnant waters. Hence their frequency in Holland, in the East and West Indies, in the flat, marshy parts of England, and the thinly-settled parts of the United States, where they diminish with the clearing of the woods and the draining of the lands. The neighbourhood of rivers or marshes, therefore, is carefully to be avoided by persons afflicted with agues. They are cured by medicines, which, at the same time that they exert a tonic influence, produce and keep up an impression upon the system greater than that communicated by the causes of the disease; such as Peruvian bark, various bitter and astringent drugs, certain metallic salts, &c.

Ague-cake; a name sometimes given to a hard tumour on the left side of the belly, lower than the false ribs, said to be the effect of intermittent fever.

Air. The air, or atmosphere in which we live and breathe, is a thin, invisible, and elastic fluid. It is material, and as such must possess weight, and act with a certain determinate pressure on all those bodies which are immersed in it. In the present article we purpose examining the general mechanical characteristics of our atmosphere, leaving its chemical nature to be discussed under that head. The various amusing and instructive experiments connected with the air-pump, will be found in the treatise on Pneumatics, in the alphabetical arrangement.

Various conjectures have been formed with respect to the height of the atmosphere; and as we know to a certainty the relative weight of a column of the atmosphere by the height to which its pressure will raise water or mercury in an empty tube, so different calculations have been founded on these data, to ascertain its extent as well as its density at different heights. If the air of our atmosphere were indeed every where of a uniform density, the problem would be very easily solved. We should in that case have nothing more to do than to find out the proportions between the height of a short pillar of air, and a small pillar of water of equal weight; and having compared the proportion which the height these bear to each other in the small, the same proportions would be certain to hold good in the great, between a pillar of water thirty-two feet high, and a pillar of air that reaches to the top of the atmosphere, the height of which we wish to know. Thus, for instance, we find a certain weight of water reaches one inch high, and a similar weight of air reaches seventy-two feet high: this then is the proportion two such pillars bear to each other on the small scale. Now, if one inch of water is equal to seventy-two feet of air, to how much air will thirty-two feet of water be equal; by the common rule of proportion we readily find, that thirty-two feet, or 384 inches, of water will be equal to 331.776 inches, which makes something more than five miles, which would be the height of the atmosphere, was its density every where the same as at the earth, where seventy-two feet of air were equal to one inch of water. But this is not really the case; for the air's density is not every where the same, but decreases as the pressure upon it decreases; so that the air becomes lighter and lighter the higher we ascend; and at the upper part of the atmosphere, where the pressure is scarcely any thing at all, the air, dilating in proportion, must be expanded to a very great extent; and therefore the height of the atmosphere must be much greater than has appeared by the last calculation, in which its density was supposed to be every where as great as at the surface of the earth. In order, therefore, to determine the height of the atmosphere more exactly, geometricians have

endeavoured to determine the density of the air at different distances from the earth.

The following sketch will give an idea of the method which some have taken to determine this density, which is preparatory to finding out the weight of the atmosphere more exactly. If we suppose a pillar of air to reach from the top of the atmosphere down to the earth's surface, and imagine it marked like a standard by inches, from the top to the bottom, and still further suppose that each inch of air, if not at all compressed, will weigh one grain, the topmost inch then weighs one grain, as it suffers no compression whatever; the second inch is pressed by the topmost with a weight of one grain, and this, added to its own natural weight or density of one grain, now makes its density, which is ever equal to the pressure, two grains. The third inch by the weight of the two inches above it, whose weight united make three grains, and these added to its natural weight give it a density of four grains. The fourth inch is pressed by the united weight of the three above it, which together make seven grains, and this added to its natural weight gives it a density of eight grains. The fifth inch being pressed by all the former fifteen, and its own weight added, gives it a density of sixteen grains, and so on descending downwards to the bottom. The first inch has a density of one, the second inch a density of two, the third inch a density of four, the fourth of eight, the fifth of sixteen, and so on. Thus the inches of air increase in density as they descend from the top, at the rate of 1, 2, 4, 8, 16, 32, 64, &c. Or if we reverse this, and begin at the bottom, we may say, that the density of each of these inches grows less upwards. If, instead of inches, we suppose the parts into which this pillar of air is divided to be extremely small, and like those of air, the rule will hold equally good in both. So that we may generally assert that the density of the air from the surface of the earth decreases in a geometrical proportion.

This being understood, should we now desire to know the density of the air at any certain height, we have only first to find out how much the density of the air is diminished to a certain standard height, and thence proceed to tell how much it will be diminished at the greatest heights that can be imagined. At small heights the diminution of its density is by fractional or broken numbers. We will suppose at once that at the height of five miles the air is twice less dense than at the surface of the earth: at two leagues high it must be four times thinner and lighter, and at three leagues eight times thinner and less dense, and so on. In short, whatever decrease it received in the first step, it will continue to have in the same proportion in the second, third, and so on; and this, as was observed, is called geometrical progression.

In proof of the great diminution in the elasticity of the air as we ascend from the earth's surface, it may be enough to state that if the common balloon was filled on ascending from the earth, the gas would burst its "silken envelope" long ere it had attained the ordinary elevation of those flying vehicles. One of the modes of ascertaining by direct experiment the diminished density, consists in filling a flask with air at a given altitude, and then closing the aperture till the experimentor arrives at the earth's surface. The aperture is afterwards opened under water, and the difference between the air above and below is indicated by the quantity of water which enters.

Dr. Cotes has also shewn, that if altitudes in the air be taken in arithmetical proportion, the rarity of the air will be in geometrical proportion. For instance,

At the altitude of … Miles above the surface of the earth, the air is	… times thinner and lighter than at the earth's surface.

And hence it is easy to prove by calculation, that a cubic inch of such air as we breathe, would be so much rarefied at the altitude of 500 miles, that it would fill a sphere equal in diameter to the orbit of Saturn.

Upon the same principle it was attempted to calculate the height of the atmosphere, by carrying a barometer to the top of a high mountain, and the density of the air at two or three different stations was easily ascertained. But so feeble are human efforts in endeavouring to comprehend and measure the works of the Creator, that this theory was soon demolished. It was found that the barometrical observations by no means corresponded with the density which, by other experiments, the air ought to have had; and it was therefore suspected that the upper parts of the atmosphere were not subject to the same laws or the same proportions as those which were nearer the surface of the earth. Another still more ingenious method was therefore devised. Astronomers know to the greatest exactness the part of the heavens in which the sun is at any one moment of time: they know, for instance, the moment at which it will set, and also the precise time at which it will rise. They soon, however, found that the light of the sun was visible before its body, and that the sun itself appeared some minutes sooner above the horizon than it ought to have done from their calculations. Twilight is seen long before the sun appears, and that at a time when it is several degrees lower than the horizon. There is then, in this case, something which deceives our sight; for we cannot suppose the sun to be so irregular in its motions as to vary every morning; for this would disturb the regularity of nature. The deception actually exists in the atmosphere: by looking through this dense, transparent substance, every celestial object that lies beyond it is seemingly raised up, in a way similar to the appearance of a piece of money in a basin filled with water. Hence it is plain, that if the atmosphere was away, the sun's light would not be brought to view so long in the morning before the sun itself actually appears. The sun itself without the atmosphere would appear one entire blaze of light the instant it rose, and leave us in total darkness the moment of its setting. The length of the twilight, therefore, is in proportion to the height of the atmosphere: or let us invert this, and say that the height of the atmosphere is in proportion to the length of the twilight: it is generally found, by this means, to be about forty-five miles high, so that it was hence concluded either that that was the actual limit of the

atmostphere, or that it must be of an extreme rarity at that height.

Dr. Arnot, in his *Treatise on Physics*, gives a very beautiful and familiar view of the effects of atmospheric pressure in changing the temperature at various altitudes. The following is his explanation of the phenomenon. If a gallon of air at the surface of the earth contain a certain quantity of heat, this must be diffused equally through the space of the gallon; but if the air be then compressed into one-tenth of the bulk, there will be ten times as much heat in that tenth as there was before; and the increase will affect the thermometer. In like manner, if by taking off pressure the gallon be made to dilate to ten gallons, the heat will be in the same proportion diffused, and any one part will be proportionably colder than before. It is known that air may be so much compressed under the piston of a close syringe, that the heat in it similary concentrated, becomes intense enough to inflame tinder attached to the bottom of the piston. This contrivance is in common use as a means of obtaining an instantaneous light, and is called the match syringe.

Now, for the reason here explained, the air near the surface of the earth, forming the bottom of the atmosphere, because condensed by the weight of the air above it, is much warmer than if it were suddenly carried higher up, where, from the pressure being less, it would be more expanded or thin. In many cases the height of mountains may be estimated by the difference of temperature observed at the bottom and at the top. While a thermometer stands at 60° at the bottom of St. Paul's Cathedral, in London, another marks only 58° at the top of the dome; and in the lofty ascent of a balloon, the thermometer soon falls to the freezing point, and below it, so that to the aeronaut the cold becomes almost insupportable.

In every part of the earth there is a certain elevation in the atmosphere, different according to the proximity to the equator, at which the thermometer never rises above the freezing point,—and this limit is called the level of perpetual congelation. In Norway, it is at five thousand feet above the level of the sea; in Switzerland, at six thousand five hundred; in Spain and Italy, at seven thousand; farther south, at Teneriffe, at nine thousand; directly under the sun, as in Central Africa, and among the Andes, in America, it is about fourteen thousand.

It appears, therefore, that the same low temperature may be met with at the equator as at the poles, by rising to find it; and we see why the snow-capt mountains are not the tenants only of high northern and southern latitudes. It is this truth which renders many parts of the tropical regions of the earth not only tolerable abodes, but as suitable as any on earth; although the ancient philosophers of Europe thought them, by reason of the great heat, uninhabitable by man, and an everlasting barrier between the northern and southern hemispheres. Much of the central land of America near the tropics is so raised, that as to agreeable temperature it rivals, an European climate, while the lightness and purity of air, and the brightness of the sun, add delightfully to its charms.

The vast expanse of table-land forming the empire of Mexico is of this kind, enjoying the immediate proximity of the sun, and yet, by its elevation of seven thousand feet above the level of the ocean, possessing the most healthful freshness The land in many parts has the fertility of a cultivated garden, and can produce naturally most of the treasures of vegetation found scattered over the diversified face of the earth. Mexico, well governed, might become a realization of paradise. The plains of Columbia, in South America, and indeed all along the ridge of the Andes, are similarly circumstanced. What a singular contrast it is, after sailing one thousand miles up the level river Magdalena, in a heat scarcely equalled on the plains of India, all at once to climb from the low region to the table-land above, where Santa Fé de Bogota, the capital of the republic, is seen smiling over interminable plains, that bear the livery of the fairest fields of Europe.

Persons not reflecting on the law which we are now illustrating, have expressed surprise that wind or air blowing down upon them from a snow-clad mountain should still be warm and temperate. The truth is, that there is just as much heat combined with an ounce of air on the mountain top as in the valley; but above, the heat is diffused through a space perhaps twice as great as when below, and therefore is less sensible. It may be the same air which sweeps over a warm plain at the side of a mountain, which then rises and freezes water on the summit, and which in an hour after, or less, is again found among the flowers of another valley, as a gentle and warm breeze.

As the temperature in different parts of the atmosphere depends thus upon the rarity of the air, and therefore upon the height, the vegetable productions of each distinct region or elevation have a distinct character; while many other peculiarities of places and climate depend on the rarity of the air.

The animal body is made up of solids and fluids, and the atmospheric pressure affects it accordingly. One has difficulty at first in believing that a man's body should be bearing a pressure of fifteen pounds on every square inch of its surface, while he remains altogether insensible to the influence; but such is the fact. Reflection discovers that his not feeling the fluid pressure, is owing to its being perfectly uniform all around. If a pressure of the same kind be even many times greater, such, for instance, as fishes bear in deep water, or as a man supports in the diving-bell, it must equally pass unnoticed. Fishes are at their ease in a depth of water where the pressure around will instantly break or burst inwards almost the strongest empty vessel that can be sent down; and men walk on earth without discovering a heavy atmosphere about them, which, however, will instantly crush together the sides of a thick iron boiler, left for a moment without the counteracting internal support of steam or air.

The fluid pressure on animal bodies, thus unperceived under ordinary circumstances, may be rendered instantly sensible by a little artificial arrangement. In water, for instance, an open tube partially immersed, becomes full to the level of the water around it, and the water contained in it is supported by what is immediately below its mouth: now, a flat fish resting closely against the mouth of the tube, would evidently be bearing on its back the whole of this weight—perhaps 100 pounds; but the fish would not thereby be pushed away, nor would it even feel its burden, because the upward pressure of the water immediately under it would just counterbalance, while the lateral pressure around would prevent any crushing effect of the mere upward and downward

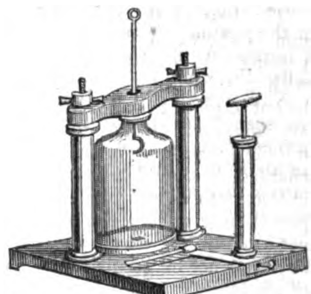
forces. But if, while the fish continued in the supposed situation, the 100 pounds of water were lifted from off its back by a piston in the tube, the opposite upward pressure of 100 pounds would at once crush its body into the tube, and destroy it. At a less depth, or with a smaller tube, the effect might not be fatal, but there would be a bulging or swelling of the substance of the fish into the mouth of the tube. In air, and in the human body, a perfectly analogous case is exhibited. A man without pain or peculiar sensation, lays his hand closely on the mouth of a vessel containing air, but the instant that the air is withdrawn from within the vessel, the then unresisted pressure of the air on the outside fixes the hand upon the vessel's mouth, causes the flesh to swell or bulge into it, and makes the blood ooze from any crack or puncture in the skin.

These last few lines closely describe the surgical operation of cupping; the essential circumstances of which are the application of a cup or glass with a smooth, blunt lip, to the skin of any part, and the extraction, by a syringe or other means, of a portion of the air from within the cup. It may facilitate to some minds the exact comprehension of this phenomenon, to consider the similar case of a small bladder or bag of india-rubber full of any fluid, and pressed between the hands on every part of its surface except one, at which part it swells, and even bursts if the pressure be strong enough. So in cupping, medicinally, the whole body, except the surface under the cup, is squeezed with a force of fifteen pounds on the square inch, while in that one situation the pressure is diminished according to the degree of exhaustion in the cup, and the blood consequently accumulates there. The mere application of a cup with exhaustion, constitutes the operation called dry-cupping: to obtain blood, the cup is removed, and the affected part is cut into by the simultaneous stroke of a number of lancet points. The cup is afterwards applied as before, so that the blood may rush forth under the diminished pressure. The partial vacuum in the cup may be produced either by the action of a syringe, or by burning a little spirit in the cup, and applying it while the momentary dilitation effected by the heat has driven out the greater part of the air. The human mouth applied upon a part, becomes a small cupping machine, and formerly, in cases of poisoned wounds, was used as such. It may be proper to add, that the late discoveries of Dr. Barry have shown that the timely application of a cupping-glass prevents the spread of contagion either in cases of poison or hydrophobia.

If a flat piece of moist leather be put in close contact with a heavy body, as a stone, it will be found to adhere to it with considerable force; and if a cord of sufficient length be attached to the centre of the leather, the stone may be raised by the cord. This effect arises from the exclusion of the air between the leather and the stone. The weight of the atmosphere presses their surfaces together with a force amounting to 15 pounds on every square inch of those surfaces in contact. If the weight of the stone be less than the number of pounds which would be expressed by multiplying the number of square inches in the surfaces of contact by 15, then the stone may be raised by the leather; but if the stone exceed this weight, it will not suffer itself to be elevated by these means.

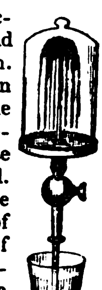
The power of flies and other insects to walk on ceilings and surfaces presented downwards, or upon smooth panes of glass in an upright position, is said to depend on the formation of their feet. This is such, that they act in the manner above described, respecting the leather attached to a stone; the feet, in fact, act as suckers, excluding the air between them and the surface with which they are in contact, and the atmospheric pressure keeps the animal in its position. In the same manner the hydrostatic pressure attaches fishes to rocks; and that "giant of the deep," the walrus, supports itself by a sort of air-pump apparatus in its feet.

Air-Bed. This is a very ingenious substitute for the ordinary feather bed. Mr. Macintosh, the patentee, employs the same elastic material in the formation of pillows for invalids. The envelope or bag which contains the air, consists of a stratum of india-rubber between two sheets of strong cotton, and a small tube is attached, to which the lips may be applied to inflate the case for use.



Air-Condenser. This is a very necessary accompaniment to the air-pump, which will presently be described. Air is compressible, and its elasticity may be beautifully illustrated in the accompanying little apparatus. It consists of a flat table, supporting a brass plate and glass receiver. The columns rising from the table serve, by the aid of a cross-bar and screws, to hold the receiver down to the plate, and prevent the escape of air. The upright syringe, with its piston and handle, is used to inject air into the receiver. Each time the piston is depressed, as much air is forced in as is equal to the internal dimensions of the tube. The wire and hook which are seen in the centre of the receiver, serves to communicate with the interior during the performance of experiments. There is a gauge at one side to show the amount of condensation.

Air-Fountain. There are two species of fountains which may be classed under this head. The most simple arrangement consists in employing the elastic force of the air compressed in a close vessel, and made to act on the surface of the water as in the pump.



The second form is exhibited in the accompanying wood-cut, and requires the aid of the air-pump to put it in operation. The receiver in which the fountain is seen to play must be made to fit air-tight on the ground brass plate beneath. The stop-cock must then be screwed into the plate of the air-pump, and a vacuum formed. After turning the stop-cock to prevent the entrance of the air, the lower extremity of the tube should be immersed in a vessel of water, and on again opening the communication the water will be seen to rise in a continuous stream, forming a beautiful *jet d'eaux*. The elevation of the water in this case is, it will be obvious, dependant on the pressure of the atmosphere, which has already been fully illustrated.

AIR GUN. This instrument owes its power to the expansive force of condensed air. We have in the previous article shown that air is highly elastic, and that it may be compressed by a common syringe.

The ball attached to the gun is intended as a reservoir for the air, and a portion of this is allowed to escape each time the trigger is drawn, so that it presses against the bullet precisely in the same way as common gunpowder.

The first account we meet with of an air-gun is in the *Elémens d'Artillerie* of David Rivaut, who was preceptor to Louis XIII. of France. He ascribes the invention to Marin of Lisseau, who presented one to Henry IV. Instruments of this kind were, however, not wholly unknown to the ancients.

The best of the modern forms of the gun is shown in the accompanying engraving. It consists of a common barrel with a spherical reservoir. It may not be out of place to add a word of cautionary advice with regard to the use of this missile apparatus. When the gun is fully charged, it should on no account be left in that state, as many balls will for a short period bear an amount of force which they would not do for any length of time. There is another circumstance of peculiar moment, namely, the effect of an increased temperature on the ball, as a slight change in the heat of the enclosed air will very materially affect the elastic force, and this circumstance has frequently been productive of explosion.

The elasticity of highly-condensed air has been estimated by Mr. Robins as equal to about one thousand times that of common air; admitting that therefore to be correct (although there seems to be great reason to suppose it much underrated), it would be necessary that air should be condensed one thousand times more than its natural state, to produce the same effect as gunpowder. There is, however, an important consideration to be attended to, viz. that the velocities with which equal balls are impelled, are directly proportional to the square-roots of the forces; so that if the air in the air-gun be condensed only ten times, the velocity with which it will project a ball will be one-tenth of that arising from gunpowder; and if the air were condensed twenty times, it would communicate a velocity equal to that of one-seventh of that of gunpowder, and so on.

Air-guns, however, project their balls with a much greater proportionate velocity than that stated above, and for this reason, that as the reservoir or magazine of condensed air is commonly very large, in proportion to the tube which contains the ball, its density is very little altered by expanding through that narrow tube, and consequently the ball is urged all the way by nearly the same uniform force as at the first instant; whereas, the elastic fluid arising from inflamed gunpowder is but very small in proportion to the tube or barrel of the gun, occupying, indeed, but a very small portion of it next the butt-end, and, therefore, by dilating into a comparatively large space as it urges the ball along the barrel, its elastic force is proportionally weakened, and it acts always less and less on the ball in the tube; whence it happens, that air condensed into a pretty large machine only ten times, will project its ball with a velocity but little inferior to that given by gunpowder; but if the valve of communication be suddenly shut again by a spring, after opening to admit some air, it will be requisite to have the condensing syringe of small bore, perhaps not more than half an inch in diameter; otherwise the force requisite to produce the compression will become so great, that the operator cannot work the machine; for, as the pressure against every square inch is about 15 lbs., and against every circular area of an inch in diameter 12 lbs., if the syringe be an inch in diameter, it will require a force of as many times 12 lbs. as the density of the air in the receiver exceeds that of the common atmosphere: so that, when the condensation is ten times, the force required will be 120 lbs.; whereas, with a half-inch bore, it will only amount to 30 lbs.

AIR-PUMP. Most of the important facts which have been presented to the notice of the reader under our article AIR, may be said to have been elicited by the employment of this instrument. Prior to the invention of the air-pump, the mechanical properties of the atmosphere were known only by a few isolated natural phenomena, and even the early air-pump was little more than an amusing toy, but in the present day it has become a valuable pneumatic machine.

In 1654, Otto de Geuricke, a counsellor at Hamburgh, and a very ingenious man, invented a method of exhausting a vessel of air by means of a syringe; and this was the first kind of air-pump made use of. He publicly exhibited a great many experiments made with it, before the Emperor of Germany at Ratisbon, which immediately attracted the attention of the philosophical world. An account of these was published by Scottus, professor of mathematics at Wirtembergh. The instrument was, however, still very awkward and imperfect. In order to try experiments with it, they were obliged to place part of the apparatus under water to keep it air-tight.

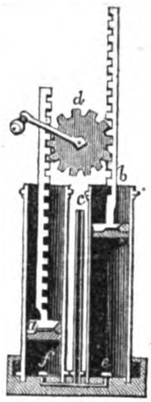
The celebrated Robert Boyle, upon hearing what Guericke had done, but without seeing any description of the apparatus, contrived an instrument for the same purpose; and his instrument, which was a single piston worked by a pinion and rack, may be considered as the origin of the present air-pump. The experiments which he made with it were both numerous and important; and he acquired such fame by them, that the exhausted vessel was called the Boylean vacuum.

Dr. Hook, a very ingenious mechanic, as we shall presently show, greatly improved this machine, by giving it two barrels and pistons. This removed a great inconvenience in the pumps with a single barrel, the pistons of which had to support the whole weight of the atmosphere, and therefore required a great force to work them. But by having two pistons, the pressure upon one is made to counterbalance that on the other, and the experimentor is thus enabled to work the instrument with the greatest ease.

He also invented the gauge, or instrument for measuring the degree of rarefaction, or exhaustion, produced in the receiver, which is a necessary appendage to the air-pump. If a barometer be included beneath the receiver, the mercury will stand at the same height as the open air, but when the receiver begins to be exhausted, the mercury will descend,

and rest at a height which is, in its proportion to the former height, as the spring of the air remaining in the receiver is to its spring before exhaustion.

The only air-pump which it may be advisable to describe in the present place, is that which is commonly employed for pneumatic purposes. It is shown in the accompanying diagram, and consists of two barrels furnished with pistons fitting air-tight.



Each of the barrels has a small aperture and valve communicating with the general orifice *c*, under the receiver of the pump. When the first piston *b* is raised, a vacuum is formed beneath, and a portion of air entering from the receiver by the valve *e* occupies the barrel.

On reversing the direction of the handle and wheel, the rack which had been raised is depressed, and the air escapes through a similar valve in the piston. Thus by the alternate elevation and depression of the racks, *a* and *b*, the rarefaction is carried on in both barrels, though a perfect vacuum can never be obtained.

The air-pumps most commonly used are made either with brass stop-cocks, or with valves of oil-skin or of leather, for preventing the return of the air into the receiver, out of which it had been exhausted. Pumps with stop-cocks, when well made, and newly put together, are generally found to rarify the air to a greater degree than those which are made with valves; but after having been used for some time, they become less accurate than those with valves. But the valves are also imperfect; as the external air, pressing upon that in the piston, prevents its rising, when the elastic force of the air in the receiver under exhaustion is much diminished. Attempts have been made, particularly by the Abbé Nollet and M. Gravesande, to perfect the construction of cocks. In Gravesande's double-barrelled pump, the cocks at the bottom of the pistons are turned by an apparatus that is moved by the handle of the pump: the piston has no valve, and the rod is connected with it by a stirrup, as in a common pump. This rod has a cylindrical part, which passes through a stirrup, and moves tightly in it through the space of about half an inch, between a shoulder above and a nut below. The stirrup supports a round plate, which has a short square tube, that fits tight into the hole of a piece of cork, and which has also a square shank that goes into the square tube. Between the plate and the cork is put a piece of thin leather, soaked in oil, and another is placed between the cork and the plate which forms the sole of the stirrup. When the winch is turned to raise the piston from the bottom of the barrel, the friction of the piston against the barrel keeps it in its place, and the rod is drawn up through the stirrup. The wheel has thus liberty to turn about an inch; and this is sufficient to turn the cock, so as to cut off the communication with the external air, and to open that with the receiver.

When this is done, the continued motion serves to raise up the piston to the top of the barrel. When the winch is turned in the opposite direction, the piston remains fixed till the cock is turned, so as to shut the communication with the receiver and open that with the external air. The cock has one perforation in the direction of its axis, and another perpendicular to it; and after reaching the centre, it passes along the axis of the cock, and communicates with the open air. By opening the above communication, the air rushes in and balances the pressure on the upper side of the piston in this barrel, so that the pressure on the other must be counteracted by the person who works the pump. In order to obviate this inconvenience, Gravesande put a valve on the orifice of the cock, by tying over it a slip of wet bladder or oiled leather; and by means of this the piston is pressed down, as long as the air in the barrel is more rarified than the outward air, just as if the valve was in the piston itself. Gravesande, and also Muschenbrock, extol the operation of this pump, as exceeding that of pumps with valves. But it is evident that no precise estimate of its performance can be obtained, whilst the pistons, valves, and leathers of the pump are prepared by steeping them in oil, and afterwards in a mixture of water and spirits of wine. With this preparation the gauge could not be brought within one-fifth of an inch of the barometer. Besides, a considerable space is left between the piston and cock, from which the air is never expelled; and if this be made very small, the pump must be worked very slowly, otherwise the air will not have time to diffuse itself from the receiver into the barrel; especially when the expelling force, or the elasticity of the air, towards the close of the operation, is very small. The rarefaction will likewise be retarded by the valve, which will not open till the air below the piston is considerably denser than the external air. The cocks in pumps of this kind are subject to become loose by use, and to admit air; an inconvenience which might, indeed, be prevented by placing the barrels in a vessel filled with oil. Those of our readers who wish for further information relative to Gravesande's pump, may find it with a figure in Gravesande's *Mathem. Elem. of Natural Philosophy*, by Desagulier, vol. ii. p. 14, &c. These pumps are now almost superseded by the cheaper and more simple contrivance of the valves, formed by tying a strip of bladder over a small hole, through which the air is allowed to pass in one direction only.

In the year 1750, the ingenious Mr. Smeaton directed his attention to the improvement of valve pumps. In considering the structure of these pumps, he observed that the principal causes of their imperfection might be traced to the difficulty of opening the valves at the bottom of the barrels, and the want of accuracy in the fitting of the piston when put down to the bottom. The first of these imperfections is owing to the smallness of the common valves, which are made of a piece of thin bladder stretched over a hole generally much less than one-tenth of an inch in diameter, and to the adhesion of the bladder to the plate upon which it is spread by reason of the oil or water with which it is moistened: as the rarefaction of the air in the receiver is continued, its spring, as we have already stated, becomes so weak that it is unable to overcome the cohesion of the bladder to the plate, the weight of the bladder, and the resistance occasioned by its being stretched. The larger the hole is, over which the bladder is laid, a proportionably greater force is exerted upon it by the included air in order to lift it up; and yet the aperture of the hole cannot be made very large, because the pressure of the incumbent air would either

burst the valve, or so far force it down into the cavity as to prevent its lying flat and close upon the plate. In order to avoid these inconveniencies, instead of one hole, Mr. Smeaton makes use of seven, all of equal size and shape, one being in the centre, and the other six round it, so that the valve is supported at proper distances by a kind of grating, formed by the solid parts between these holes, and resembling a honeycomb; and that the points of contact between the bladder and grating may be as few as possible, the holes are hexagonal, and the partitions are filed almost to an edge. The breadth of these hexagons is three-tenths of an inch, and consequently the surface nine times larger than common; and as the circumference is three times greater than that of the common valve, and the cohesion to be overcome is, in the first moment of the air's exerting its force, proportional to the circumference of the hole, the valve over any of these holes will be raised with three times more ease. Besides, the raising of the valve over the centre hole is aided on all sides by those that are placed round it; and as they all contribute as much to raise the bladder over the centre hole, as the air immediately acting under it, the valve will be raised with double the ease already supposed, or with a sixth part of the force commonly necessary. After the bladder begins to rise, it will expose a greater surface to the air underneath, which will cause it to move more easily.

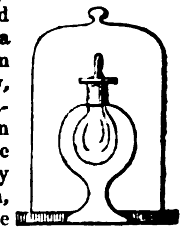
The celebrated experiment of the Madgeburgh hemispheres will serve as a practical illustration of the use of the air-pump.

Two hollow hemispheres, *b d*, constructed of brass, as represented in the diagram, are so formed, that when placed mouth to mouth they shall be in air-tight contact. They are furnished with handles, *c d*, one of which may be screwed off.

In the neck to which this handle is screwed, is a tube furnished with a stop-cock. The handle being screwed off, let the hemisphere be screwed on the pump plate, and the other hemisphere being placed over it, let the stop-cock be opened so as to leave a free communication between the interior of the sphere and the exhausting tube of the air-pump. The pump being now worked, the interior of the sphere will form the receiver from which all communication with the external air is cut off, and rarefaction will be produced in it to any degree which may be desired. This being effected, let the stop-cock be closed; and let the sphere be detached from the pump plate, and the handle screwed upon it. If then the two handles be drawn in opposite directions, so as to pull the hemispheres from one another, it will be found that they will resist with considerable force. If the diameter of the sphere be 6 inches, its section through the centre will be about 28 square inches. The hemispheres will be pressed together by a force amounting to 15 pounds for every square inch in the section. If 28 be multiplied by 15, we shall obtain 420, which is the amount of the force with which the hemispheres will be held together. If one of the handles be placed on a strong hook, and a weight of 400 pounds be suspended from the other, the weight will be supported by the pressure of the atmosphere.

This is one of the earliest experiments in which the effects of atmospheric pressure were exhibited. Otto Guericke, the inventor of the air-pump, constructed, in 1654, a pair of such hemispheres one foot in diameter. The section through the centre of these were about 113 square inches, which multiplied by 15 gives a pressure amounting to nearly 1,700 pounds. If the exhaustion were complete, the hemispheres would be held together by this force; but, even though incomplete, they were still able to resist a prodigious force tending to draw them asunder.

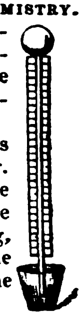
Another very beautiful experiment tending to illustrate the use of the air-pump and the phenomena of respiration may now be adverted to. The apparatus for the purpose is shewn in the figure.



It consists of a receiver placed on the pump plate, and enclosing a globular-shaped glass vessel, within which is contained a bladder. Now, in the ordinary process of respiration a partial vacuum is formed in the chest by the elevation of the ribs, and the air passing down by the ordinary passage of the mouth, enters the lungs and oxygenizes the blood. In the little apparatus above referred to, a vacuum is formed by the air-pump, and the bladder immediately expands; on the readmission of the air, it returns to its original dimensions, so that a series of expansions and contractions may readily be produced very analogous to the operations of nature.

Air Remedies, in *Surgery*. The application of gaseous matters to the purposes of surgery has not been sufficiently attended to. There is reason to believe that several æriform substances might be employed locally as well as internally, to considerable advantage; but it would exceed the limits we have prescribed to this department of our work, were we to adduce all the facts that might be brought forward to illustrate the medicinal powers of air in its different combinations. The application of fixed air, or carbonic acid gas, by means of fermentation, in cases of fetid and gangrenous ulcers is now well known. It has been advantageously used also in malignant ulcers of the nose, tongue, and mouth, as well as in caries of the bones.

Fixed air is plentifully obtained from a mixture of alkaline or chalky substances with vitriolic acid; and during the effervescence, applying the gas which is extricated immediately to the morbid part; or, by impregnating water with it, compresses may be soaked in the water, and laid frequently over the seat of the disease. The antiseptic properties of this gas may be shewn by suspending a piece of meat in common air, and a similar portion in the carbonic acid. It will be found that the one will retain its freshness, while the other will speedily decay. See Carbonic Gas and Chemistry.

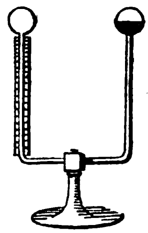


Air-Thermometer. The great susceptibility of air to the influence of caloric, has induced the chemist to employ it as a substitute for mercury and spirit of wine in the construction of thermometers.

The instrument which he employs consists of a tube furnished with a bulb containing air. The cup beneath is intended to hold a little coloured fluid, and if a portion of the air in the bulb be expelled by heat, it will, on cooling, re-ascend the tube, and indicate changes in the temperature of the surrounding bodies by the rise or fall of the coloured fluid.

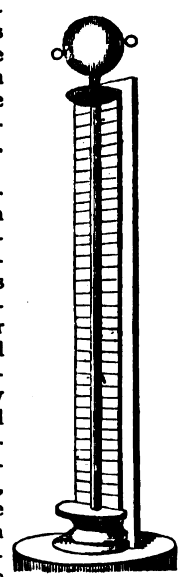
The double-air, or differential thermometcr, is a

modification of the above. This thermometer consists of a small glass tube bent into the shape of the letter U, and terminating at each extremity in a small hollow ball nearly of the same size; the tube contains a little sulphuric acid tinged red with carmine, and sufficient to fill the greatest part of it. The glass balls are full of air, and both communicate with the intermediate tube.



To one of the legs of the tube, as shown above, is affixed a small ivory scale, divided into 100 degrees; and the sulphuric acid is so disposed, that in the graduated leg its upper surface stands opposite to the part of the scale marked 0. The glass ball attached to the leg of the instrument to which the scale is attached, is by way of distinction called the focal ball. Suppose this thermometer brought into a warm room, the heat will act equally upon both balls, and expanding the included air equally in each, the liquor in the tube will remain stationary. But suppose the focal ball exposed to heat while the other ball is not; in that case, the air included in the focal ball will expand, while that in the other is not affected. It will therefore press more upon the liquid in the tube, which will of course advance towards the cold ball, and therefore the liquid will rise in the tube above 0, and the rise will be proportional to the degree of heat applied to the focal ball. This thermometer, therefore, is peculiarly adapted for ascertaining the degree of heat accumulated in a particular point, while the surrounding atmosphere is but little affected, as happens in the focus of a reflecting mirror. No change in the temperature of the room in which the instrument is kept is indicated by it, while the slightest alteration in the spot where the focal ball is placed is immediately announced by it.

Air-Thermometer, in *Electricity*. There are several forms of this apparatus described by the early electricians, neither of which are at all equal either on the score of utility or simplicity to the accompanying instrument by Mr. Ronalds.



This must be a much more substantial piece of apparatus than that employed for chemical purposes, and the ball should be somewhat larger in proportion to its size. It consists of a stand supporting a tube and bulb, the latter being provided with two wires and rings. If the object be to ascertain the amount of expansion by the electric shock, when passed through common air, a communication is made between the machine and the rings by a chain, and the expansion is shown by the depression of the coloured fluid in the tube. If any other gas be experimented on, a vacuum must be first formed by the air-pump, and the gas introduced.

Air-Vessels in *Navigation*. It is important that we should here notice an arrangement of tubes under this name, which has been introduced for the construction of ships at sea, and more especially for life-boats. Mr. Greathead, the inventor, first suggested *air-tanks*, but afterwards substituted long tube-formed air vessels, which were carried round the planking, and arranged in strata beneath the decks. In the event of a boat thus protected shipping a heavy sea, a number of persons may still be supported by the aid of the air-vessels. But the great use of this contrivence would be found in the event of a vessel foundering at sea. This circumstance has attracted the attention of a very ingenious gentleman of the name of Watson, who in a lecture lately delivered in the London Institution, demonstrated the practicability of applying air-vessels of this description to the whole British navy.

Ajutage, or Adjutage, in *Hydraulics*; the most essential part of any artificial fountain or water-pipe. There is so much discrepancy in the published experiments of various authors on this subject, that it may be advisable to give our readers an analysis of those most distinguished for their accuracy. We may commence with those of Bossut and Prony. The following is a comparison, by M. M. Bossut and Prony, of the theoretical with the real discharges from a simple ajutage one inch in diameter.

Constant weight of the water in the reservoir above the centre of the orifice.	Theoretical discharge through a circular orifice one inch in diameter.	Real discharges in the same time through the same orifice.	Ratio of the theoretical to the real discharges.

To determine the relative quantities discharged by orifices of different forms, we must have recourse to the invaluable labours of Bossut, Michellotti, Smeaton, Poleni, Venturi, and Eytelwein, and we may commence with the experiments of Bossut, Michellotti, Brindley, and Smeaton, as deduced by Mr. Adcock:

That the quantities of fluid discharged in equal

times from different sized apertures, the altitude of the fluid in the reservoir being the same, are to each other nearly as the area of the apertures.

That the quantities of water discharged in equal times by the same orifice under different heads of water, are nearly as the square roots of the corresponding heights of the water in the reservoir above the centre of the apertures.

That, in general, the quantities of water discharged in the same time, by different apertures under different heights of water in the reservoir, are to one another in the compound ratio of the areas of the apertures, and the square roots of the altitudes of the water in the reservoirs.

That on account of the friction, the smallest orifice discharges proportionally less water than those which are larger and of a similar figure, under the same heads of water.

That from the same cause, of several orifices whose areas are equal, that which has the smallest perimeter will discharge more water than the other, under the same altitudes of water in the reservoir. Hence, circular apertures are most advantageous, as they have less rubbing surface under the same area.

That, in consequence of a slight augmentation which the contraction of the fluid vein undergoes, in proportion as the height of the fluid in the reservoir increases, the expenditure ought to be a little diminished.

That the discharge of a fluid through a cylindrical horizontal tube, the diameter and length of which are equal to one another, is the same as through a simple orifice.

That if the cylindrical horizontal tube be of a greater length than the extent of the diameter, the discharge of water is much increased.

That the length of the cylindrical horizontal tube may be increased with advantage to four times the diameter of the orifice.

That the diameters of the apertures and altitudes of water in the resevoir being the same, the theoretic discharge through a thin aperture, which is supposed to have no contraction in the vein, the discharge through an additional cylindric tube of greater length than the extent of its diameter, and the actual discharge through an aperture pierced in a thin substance are to each other as the numbers 16, 13, 10.

That the discharges by different additional cylindric tubes under the same head of water are nearly proportional to the areas of the orifices, or to the squares of the diameters of the orifices.

That the discharges by additional cylindric tubes of the same diameter under different heads of water are nearly proportional to the square roots of the head of water.

That from the two preceding corollaries, it follows, in general, that the discharge during the same time, by different additional tubes, and under different heads of water in the reservoir, are to one another nearly in the compound ratio of the squares of the diameters of the tubes, and the square roots of the heads of water.

The following are deductions from the experiments of M. Venturi:

That if the part of a compound tube nearest the reservoir have the form of a contracted vein, the expenditure will be the same as if the fluid were not contracted at all.

That if to the smallest diameter of a cone, a cylindrical pipe be attached, of the same diameter as the least section of the contracted vein, the discharge of the fluid will, in a horizontal direction be lessened by the friction of the water against the side of the pipe.

That if the same tube be applied in a vertical direction, the expenditure will be augmented, on the principle of the gravitation of falling bodies; consequently, the greater the length of pipe the more abundant is the discharge of fluid.

That if the additional compound tube have a cone applied to the opposite extremity of the pipe, the expenditure will, under the same head of water, be increased in the ratio of 24 to 10.

In order to produce this singular effect, the cone nearest the reservoir must be of the form of the contracted vein, which will increase the expenditure in the ratio of 12.1 to 10. At the other extremity of the pipe, a truncated conical tube must be applied, of which the length, nearly nine times the diameter at the smallest part, and its outward diameter must be 1.8. This additional cone will increase the discharge in the proportion of 24 to 10.

That in vertical tubes, the upper ends of which have the form of the contracted vein, the quantity of water discharged is that which corresponds with the height of the fluid above the inferior extremity of the tube.

That in compound conical tubes, the discharge of the fluid is increased in the proportion of the area of the section of the contracted vein, whatever may be the position of the tube, provided that its internal figure be adapted throughout to the lateral communication of the motion.

That by varying the divergence of the sides of the tubes, the lateral communication of motion has a maximum and a minimum of effect. The minimum of effect is when the angle made by the sides of the tube with each other exceeds sixteen degrees, and the maximum effect is when the same angle is about three degrees.

Discharge by bent tubes.—Experiments by M. Venturi.

Height of water in the reservoir 32.5 inches.	Time in which 4 Paris cubic feet were discharged.
Cylindrical horizontal tube, having the conical end of the form of the contracted vein:	
Diam. 14.5 lines.—Length 15 inches...	45″
Cylindrical curved tube, having a conical end similar to the last:	
Diam. 14.5 lines.—Length 15 inches..	50″
Cylindrical angular tube, having a conical end similar to the two preceding:	
Diam. 14.5 lines.—Length 15 inches...	70″

ALBUMEN. This substance owes its name to the Latin term for the white of egg. The white of an egg, however, is not pure albumen. It contains also some mucus, soda, and sulphur: but as albumen is never found perfectly pure, and as no method is known of separating it without at the same time altering the properties of albumen, chemists are obliged to examine it while in combination with these bodies.

Albumen dissolves readily in water, and the solution has the property of giving a green colour to vegetable blues, in consequence of the soda which it contains. When albumen it heated to the temperature of 165°, it coagulates into a white solid mass; the

consistency of which, when other things are equal, depends in some measure on the time during which the heat was applied. The coagulated mass has precisely the same weight that it had while fluid. This property of coagulating when heated is characteristic of albumen, and distinguishes it from other bodies.

The taste of coagulated albumen is quite different from that of liquid albumen: its appearance, too, and its properties, are entirely changed; for it is no longer soluble, as before, either in hot or cold water.

The coagulation of albumen takes place even though air be completely excluded; and even when air is present, there is no absorption of it, nor does albumen in coagulating change its volume. Acids have the property of coagulating albumen, as Scheele ascertained. Alcohol also produces, in some measure, the same effect. Heat, then, acids and alcohol, are the agents which may be employed to coagulate albumen.

It is remarkable, that if albumen be diluted with a sufficient quantity of water, it can no longer be coagulated by any of these agents. Scheele mixed the white of an egg with ten times its weight of water, and then, though he even boiled the liquid, no coagulation appeared. Acids, indeed, and alcohol, even then coagulated it; but they also loose their power if the albumen be diluted with a much greater quantity of water, as has been ascertained by many experiments. Now, when water is poured into albumen, its integrant particles must be farther separated from each other, and their distance must increase with the quantity of water with which they are diluted. We see, therefore, that albumen ceases to coagulate wherever its particles are separated from each other beyond a certain distance. That no other change is produced, appears evident from this circumstance, that whenever the watery solution of albumen is sufficiently concentrated by evaporation, coagulation takes place, upon the application of the proper agents, precisely as formerly.

It does not appear that the distance of the particles of albumen is changed by coagulation; for coagulated albumen occupies precisely the same sensible space as liquid albumen.

Now, to what is the coagulation of albumen owing? We can conceive no change to take place from a state of liquidity to that of solidity, without some change in the figure of the particles of the body which has undergone that change. Now such a change may take place three ways: 1. The figure may be changed by the addition of some new molecules to each of the molecules of the body. 2. Some molecules may be abstracted from every integrant particle of the body. 3. Or the molecules of which the integrant particles are composed, may enter into new combinations, and form new integrant particles, whose form is different from that of the old integrant particles. Some one or other of the following circumstances must take place during the coagulation of albumen.

Scheele and Fourcroy have described the coagulation of albumen to the first of these causes, namely, to the addition of a new substance. According to Scheele, caloric is the substance which is added. Fourcroy, on the contrary, affirms that it is oxygen.

Scheele supported his opinion with that wonderful ingenuity which shone so eminently in every thing which he did. He mixed together one part of the white of an egg, and four parts of water, added a little pure alkali, and then dropt it into as much muriatic acid as was sufficient to saturate the alkali. The albumen coagulated. But when he repeated the experiment, and used carbonate of alkali, instead of pure alkali, no coagulation ensued. In the first case, he says, there was a double decomposition: the muriatic acid separated from a quantity of caloric, with which it was combined, and united with the alkali; while, at the same instant, the caloric of the acid united with the albumen, and caused it to coagulate. The same combination could not take place when the alkaline carbonate was used, because the carbonic acid gas carried off the caloric, for which it has a strong affinity.

Fourcroy observes, in support of his opinion, that the white of an egg is not at first capable of forming a hard coagulum, and that it only acquires that property by exposure to the atmosphere. It is well known that the white of a new laid egg is milky after boiling; and that if the shell be covered over with grease to exclude the external air, it continues long in that state; whereas the white of an old egg, which has not been preserved in that manner, forms a very hard, tough coagulum. These facts are undoubted; and they render it extremely probable, that albumen acquires the property of forming a hard coagulum only by absorbing oxygen: but they by no means prove that coagulation itself is owing to such an absorbtion. And since coagulation takes place without the presence of air, and since no air, even when it is present, is absorbed, this opinion cannot be maintained without inconsistency.

The only substance which can be supposed to leave albumen during coagulation, since it does not lose its weight, is caloric. We know that in most cases where a fluid is converted into a solid, caloric is actually disengaged. It is extremely probable, then, that the same disengagement takes place here. But the opinion has not been confirmed by any proof. Fourcroy indeed says, that in an experiment made by him, the thermometer rose a great number of degrees. But as no other person has ever been able to observe any such thing, it cannot be doubted that this philosopher has been misled by some circumstance or other to which he did not attend.

The coagulation of albumen resembles exactly what takes place when concentrated silicated potash is exactly saturated with muriatic acid. The mass slowly assumes an opal colour, and at last concentrates into a solid gelatinous mass. Now this jelly consists of the particles of silica combined with each other, and with a certain portion of water. These particles were formerly held in solution by the potash; that is to say, the affinity of the silica for potash was superior to the cohesive force which exists between the particles of silica. The muriatic acid, by saturating the potash, diminished the force of its affinity for the silica. The cohesive force of the silica, now superior, causes it to combine in masses, consisting of a certain portion of silica and water. These masses, equally diffused through the liquid, and at such small intervals as to cohere together, gives the whole a gelatinous form. Something like this seems to take place with respect to the albumen. Its particles, combined with water and also with soda, are all kept at equal distances in the liquid; because this affinity just balances their cohesive force. But when heat is applied, this affinity is diminished by the additional elasticity, or tendency to separate, given to the water and the soda. The cohesion of the albumen, now superior, causes its particles to combine in sets, form-

ing solid bodies, equally distant from each other, and cohering together. Hence the gelatinous form, and the solidity of the coagulum, always inversely proportional to the quantity of water present. Thus it appears, that whatever diminishes the affinity between the water and soda and the albumen, occasions its coagulation, by allowing its cohesive force to act.

Albumen, then, is capable of existing in two states; the one before it has been coagulated, and the other after it has undergone coagulation. Its properties are very different in each. It will be proper, therefore, to consider them separately.

Albumen in its natural state, or uncoagulated, is a glary liquid, having little taste, and no smell. When dried spontaneously, or in a low heat, it becomes a brittle, transparent glassy-like substance; which, when spread thin upon surfaces, forms a varnish, and is accordingly employed by book-binders for that purpose. When thus dried, it has a considerable resemblance to gum arabic, to which also its taste is similar. The white of an egg loses about four-fifths of its weight in drying. It is still soluble in water, and forms the same glary liquid as before.

From the experiments of Dr. Bostock, it appears that when one part of this dry albumen is dissolved in nine parts of water, the solution becomes perfectly solid when coagulated by heat; but if the albumen amounts only to $\frac{1}{15}$th of the liquid, then, though coagulation takes place, the liquid does not become perfectly solid, but may be poured from one vessel to another.

When one grain of albumen is dissolved in 1000 grains of water, the solution becomes cloudy when heated.

Uncoagulated albumen soon putrefies unless it be dried; in which state it does not undergo any change. It putrefies more readily when dissolved in a large quantity of water than when concentrated. The smell of white of egg, allowed to run into putrefaction, resembles that of pus.

It is insoluble in alcohol or ether, which immediately coagulate it, unless it be mixed with a great proportion of water, in which case even acids have no effect.

When acids are poured upon it, coagulation takes place equally; but several of them have the property of dissolving it again when assisted by heat. This at least is the case with sulphuric acid. The solution is of a green colour, and does not soon blacken, even when boiled. It is the case also with nitric acid, and probably also with muriatic acid. Nitric acid first disengages some azotic gas; then the albumen is gradually dissolved, nitrous gas emitted, oxalic and metallic acids formed, and a thick oily matter makes its appearance on the surface.

Albumen, Vegetable. The discovery of albumen in vegetables is due to Fourcroy. This chemist having observed that the clarification of the expressed juices of the antiscorbutic plants was effected by the spontaneous coagulation of their colouring matter at the temperature of boiling water, was induced to examine whether this property did not depend on the presence of albumen. For this purpose, having obtained the juice of two pounds of young cresses, he filtered it while cold, through blotting paper, and by this means separated the grosser parts of the colouring fecula: the liquor was, however, still of a bright green, but upon being exposed in a broad shallow vessel to the air, at a temperature of about 80° Fah., in two hours it became turbid, and deposited a greenish matter, becoming itself almost colourless; in this state it was exposed to the heat of boiling water, and in a few minutes there separated a large quantity of whitish flocculent matter. Another portion of the same clarified liquor being exposed to the air, deposited at the end of two days a similar coagulum; and the same effect was produced on the third portion by the addition of sulphuric acid. The substance thus obtained being first repeatedly washed in cold water, exhibited all the properties of animal albumen. It was easily and quickly dissolved by any of the alkalies; it experienced no change in boiling water, except that of becoming more solid; it converted the purple juice of mallows to green, and by distillation, yielded a notable quantity of ammonia: when exposed with a little water to a warm air, it swelled considerably, exhaled a fetid ammoniacal odour, and gave all the usual signs of active putrefaction; hence explaining the reason of the rank disagreeable smell that characterises the spontaneous decomposition of all the cruciform plants. When dried, by pressure between two pieces of paper, it exhibited a considerable degree of ductility and transparence, like glue.

Albumen was afterwards found in the roots of various vegetables, especially of the rumexpatientia; also in wheat and the farinaceous seeds; and in general in all the green and succulent parts of plants. The acid pulps of fruits are totally destitute of this substance, but abound with jelly; and it is the opinion of Fourcroy, that in all these cases there is a conversion of albumen into jelly, by the gradual evolution of the acid, and consequent fixation of oxygen.

Alchemy. This ancient and highly poetical forerunner of the science of chemistry has much that is interesting in its early history and progress. Sober utilitarian science would have found but few supporters in the early dawn of alchemy, but the visionary prospect of realizing vast treasures by the fortunate labour of a happy day, nay of a single moment, when the stars were propitious, induced many persons to waste their lives and fortunes in the vague attempt at discovering the formation of the philosopher's stone, the elixir of life, or some other equally absurd phantasy.

The golden age of alchemy most ominously commenced with the conquests of Arabian fanaticism in Asia and Africa, the destruction of the Alexandrian library, and the subjection of Europe to the basest superstition, and the most profound ignorance. The Saracens, lively, subtle, credulous, and nurtured in fables of talismans, and the celestial influences, admitted with eager faith the wonders of alchemy, and condescended to receive instruction from slaves whom they had conquered; the rage of making gold spread through the whole Mahometan world, and in the splendid courts of Almanzor, Haroun-al-Raschid, and Abdallah Almammon, the professors of the Hermetic art found patronage, disciples, and emolument. Geber, Rhazes, Albufaragius, and Avicenna, the most celebrated physicians and chemists of the Arabian school, were deeply tinged with the prevailing insanity. From the 10th to the 13th century, little is known concerning the state of alchemical studies; the descendants of the Arabian warriors had begun to acquire a taste for science when their thrones were shaken by the Crusades, and finally overthrown by the desolating deluge of the Turkish barbarians. The

arts again retiring from Egypt and Syria, rested for a moment at Constantinople, and then withdrew to the western provinces of Europe. In the 13th century Albertus Magnus, Roger Bacon, and Raymond Lully, appeared as the great revivers of alchemy and chemistry; for from this time, although alchemical pursuits were esteemed the noblest and most important, yet they ceased to occupy entirely the attention of experimental philosophers. The writings of these able men raised the study of alchemy to a degree of credit which it little merited, especially among the ecclesiastics, who possessed at that time almost all the learning of the age; and even a pope, John XXII., was weak enough to assert, in his treatise on the art of transmutation, that he had himself made 200 ingots of gold, of the weight of 100 pounds each. The 15th century exhibits the same combination of chemistry and alchemy; but in which it is pleasing to observe a great dimunition of reserve with regard to the processes of common chemistry, which are for the most part told in very plain language by the men who, when treating of alchemy, are utterly unintelligible. The great authors during this period are George Ripley and Basil Valentine. A portrait of the latter philosopher, and a view of his study, may not be out of place, especially as it will serve to convey a notion of a laboratory of the period.

Hitherto alchemy had been confined to the single object of changing the baser metals into silver and gold, and the materia medica consisting wholly of vegetable and animal preparations, there existed little or no connexion between the chemists and physicians. The prevalence, however, of the leprosy, and the rise and rapid progress of a variety of diseases, rendered it necessary to have recourse to more potent remedies. The Asiatic practice of physic, with regard to the use of mercury, was introduced with the happiest effects by Carpus; antimony found an able advocate in Basil Valentine, whose *Currus Triumphalis Antimonii* is a curious mixture of enthusiasm and knowledge. The credit of the Galenists began to be shaken, and chemistry by thus associating to itself the most philosophical of the three learned professions, acquired an immense accession of abilities. The unexpected success which attended the first medical use of chemical preparations, awakened a new hope in the minds of the alchemists; and this was no less than the discovery of an universal medicine which should heal all disorders, and prolong the duration of human existence to an indefinite period. The great authors of this sect were Paracelsus and Vanthelmont, who by their vigorous use of opium and mercury, effected a number of important cures, impossible to the common Galenical practice of the age. About the same time flourished Henry Cornelius Agrippa and George Agricola, the first of whom, half knave and half enthusiast, belongs decidedly to the alchemical party; but the latter, though bewildered in youth by the false philosophy of his time, made ample amends to the cause of true science in his maturer years, by his admirable treatise on metallurgy and mineralogy. From this time we meet with few authors of reputation who wrote professedly on alchemy, though a kind of half belief in the thing still clung about even the most eminent chemists, as may be clearly traced in their writings. A bold attempt to support the falling cause was made in the beginning of the 17th century by the Rosicrucians, a secret society which originated in Germany, and attracted the attention of the rest of Europe for 25 years. By pretending, however, to too much, even to more than the ancient chemists when even in the plenitude of their power and influence ever arrogated to themselves—the fraternity made few converts, and speedily sunk into total discredit.

Volumes have been written on the subject of alchemy: no person, however, has done such perfect justice to this interesting part of chemistry as professor Brande, who, amongst other authorities in favour of the successful labours of the alchemists, quotes that of Bergman, himself a distinguished chemist. In summing up the evidence of various authors for and against the possibility and probability of transmutation, Bergman observes, that "although most of them are deceptive, and many uncertain, some bear such character and testimony, that unless we reject all historical evidence, we must allow them entitled to confidence." For my part, the perusal of the histories of transmutation appears to me to furnish solid grounds for a diametrically opposite opinion. They are all of a most suspicious character: sometimes the fraud was open and intentional, seconded by juggling dexterity; at other times the performers deceived themselves; they purchased what was termed a powder of projection, prepared by the adepts, containing a portion of gold, and when they threw it into the fire with mercury, and found that portion of gold remaining in their crucible, they had not wit enough to detect its source; but the cases which are quoted as least exceptionable, are often exactly those which are really impossible; I mean, where the weight of the powder of projection, and of the lead or other base metal taken conjointly, was exceeded by that of the gold produced. Such is Hearne's history of Payknl's transmutation; who, with six drachms of lead and one of powder, produced an ingot that was coined into 147 ducats; and many others. But the most celebraled history of transmutation is that given by Helvetius, in his brief of the *Golden Calf:* discovering the rarest miracle in nature, how by the smallest portion of the philosopher's stone a great piece of common lead was totally transmuted into the purest transplendent gold, at the Hague, in 1666: and, as it is a luminous epitome of all that has been done on this subject, it may be better briefly to abridge the proceedings: "The 27th day of December, 1666, in the afternoon, came a stranger to my house at the Hague in a plebeick habit, of honest gravity and serious authority, of a mean stature, and a little long face, black hair, not at all curled, a beardless chin, and about 44 years (as I guess) of age, and born in North Holland. After salutation, he beseeched me

with great reverence to pardon his rude accesses, for he was a lover of the pyrotechnical art, and having read my treatise against the sympathetic powder of Sir Kenelm Digby, and observed my doubt about the philosophic mystery, induced him to ask me if I really was a disbeliever as to the existence of an universal medicine which would cure all diseases, unless the principal parts were perished, or the predestined time of death come. I replied, I never met with an adept, or saw such a medicine, though I had fervently prayed for it. Then I said, surely you are a learned physician? No, said he; I am a brass-founder, and a lover of chemistry. He then took from his bosom-pouch a neat ivory box, and out of it three ponderous lumps of stone, each about the bigness of a walnut. I greedily saw and handled for a quarter of an hour this most noble substance, the value of which might be somewhere about twenty tons of gold, and having drawn from the owner many rare secrets of its admirable effects, I returned him this treasure of treasures with a sorrowful mind, humbly beseeching him to bestow a fragment of it upon me in perpetual memory of him, though but the size of a coriander-seed. No, no, said he; that is not lawful: though thou wouldst give me as many golden ducats as would fill this room—for it would have particular consequences—and if fire could be burned of fire, I would at this instant rather cast it all into the fiercest flames. He then asked if I had a private chamber whose prospect was from the public street; so I presently conducted him to my best-furnished room backwards, which he entered," says Helvetius (in the true spirit of Dutch cleanliness), "without wiping his shoes, which were full of snow and dirt. I now expected he would bestow some great secret on me, but in vain. He asked for a piece of gold, and opening his doublet, showed me five pieces of that precious metal which he wore upon a green riband, and which very much excelled mine in flexibility and colour, each being the size of a small trencher. I now earnestly again craved a crumb of the stone, and at last, out of his philosophical commiseration, he gave me a morsel as large as a rape-seed: but, said I, this scanty portion will scarcely transmute four grains of lead. Then, said he, deliver it me back; which I did, in hopes of a greater parcel: but he, cutting off half with his nail, said, even this is sufficient for thee. Sir, said I, with a dejected countenance, what means this? And he said, even that will transmute half an ounce of lead. So I gave him great thanks, and said I would try it, and reveal it to no one. He then took his leave, and said he would call again next morning at nine. I then confessed, that while the mass of his medicine was in my hand the day before, I had secretly scraped off a bit with my nail, which I projected on lead, but it caused no transmutation, for the whole flew away in fumes. Friend, said he, thou art more dexterous in committing theft than in applying medicine: hadst thou wrapt up thy stolen prey in yellow wax, it would have penetrated and transmuted the lead into gold. I then asked if the philosophic work cost much, or required long time; for philosophers say that nine or ten months are required for it. He answered, their writings are only to be understood by the adepts, without whom no student can prepare this magistery. Fling not away, therefore, thy money and goods in hunting out this art, for thou shalt never find it. To which I replied, as thy master showed thee, so mayest thou perchance discover something thereof to me, who know the rudiments; and therefore it may be better to add to a foundation than begin anew. In this art, said he, it is quite otherwise; for unless thou knowest the thing from head to heel, thou canst not break open the glassy seal of Hermes. But enough; to-morrow at the ninth hour, I will tell you the manner of projection. But Elias never came again: so my wife, who was curious in the art whereof the worthy man had discoursed, teazed me to make the experiment with the little spark of bounty the artist had left me. So I melted half an ounce of lead, upon which my wife put in the said medicine: it hissed and bubbled, and in a quarter of an hour the mass of lead was transmuted into fine gold, at which we were exceedingly amazed. I took it to the goldsmith, who judged it most excellent, and willingly offered fifty florins for each ounce."

Such is the celebrated history of Elias the artist, and De Helvetius; and such may be considered as the general tenour of the alchemical attempts of the period. We must not, however, omit to state, that the alchemists have materially assisted in the advancement of chemistry, both by real discoveries, and by the invention of nearly all the implements now employed in chemical research.

It is not a little remarkable, that while Europeans have studied alchemy for the express purpose of acquiring gold, the Chinese, so early as the reign of Woote (B. C. 140), were engaged in pursuing the same object. It is stated, that one Le-shaou-keun (a priest of the Taou sect) advised his majesty to re-establish the worship of the god of the furnace; asserting that from red oxide, gold could be obtained. He also affirmed, that if temples were erected to the Sëen genii, or spirits, they would come and confer on his majesty a woo-sze-yŏ, a medicine that would prevent death. The emperor, in compliance with the advice given, worshipped the furnace, and ordered priests to put to sea in quest of the island Pung-lae, the abode of the immortals. It is said that Le-shaou-keun, like many in the west, died just before he succeeded in making gold. During the 12th year of this reign, as is gravely stated, the priest Lan-ta thus addressed his majesty: "Having repeatedly put to sea, I have seen the spirit Gan-te, who has instructed me how to make gold, and how to obtain the medicine that tends to immortality; and can also induce them to visit this place." Lan-ta in consequence received an important appointment, and a princess was given him in marriage. His deceptive arts however being discovered, he was in consequence beheaded.

ALCOHOL. This term is applied exclusively to the purely spirituous portions of those fluids which have undergone the vinous fermentation.

Alcohol is considerably lighter than water, viz. in the proportion of 800 or 820 to 1000. The lightest that can be obtained, by simple distillation from spirit of wine, has the specific gravity of 825. By the intervention of substances which strongly attract water, Chaussier brought it to the specific gravity of 798, and Lovitz and Saussure, jun. to 791 or 792. Alcohol of the specific gravity 820 still contains, according to Lovitz, about $\frac{1}{10}$th its weight of water. When of the specific gravity 920, it has been called *proof spirits*; the term *above proof* being used to denote a spirit lighter than this, and *under proof* one which contains a larger proportion of water. Rectified spirit is directed by the *London Pharmacopœia* to have the specific gravity of 835, but it seldom exceeds

840. The quantity of alcohol and water in mixtures of different specific gravities, may be learned from Mr. Gilpin's copious tables, of which the following is an abstract.

Table showing the specific gravity of the mixture of alcohol and water.

Centesimal parts of the Mixture.	Specific Gravities. According to Chaussier.	According to Gilpin (last Table.)
Alcohol . . . 100	0.7980	0.825
95	0.8165	0.83887
90	0.8340	0.85244
85	0.8485	0.86414
80	0.8620	0.87606
75	0.87525	0.88762
70	0.8880	0.89883
65	0.9005	0.90941
60	0.9120	0.91981
55	0.9230	0.92961
50	0.9334	0.93882
45	0.94265	0.94726

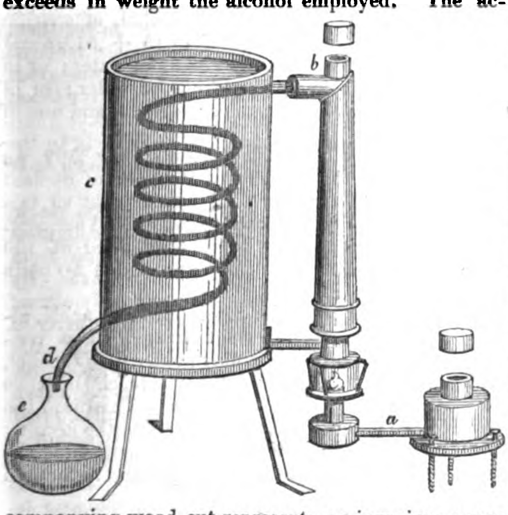
Alcohol unites chemically with water; and caloric is evolved during this union. Equal measures of alcohol and water, each at 50° Fahrenheit, give by sudden admixture an elevation of nearly 20° of temperature; and equal measures of proof spirit and water an increase of 9½°. The bulk of the resulting liquid is less also than that of the two before admixture.—Thus a pint of alcohol and a pint of water, when the mixture has cooled to the temperature of the atmosphere, falls considerably short of two pints.

Alcohol is highly inflammable. During its combustion, carbonic acid is generated; no charcoal appears; and a quantity of water is produced which exceeds in weight the alcohol employed. The accompanying wood-cut represents an ingenious apparatus employed by Lavoisier for the purpose of ascertaining this fact.



It consists of a spirit-lamp *a*, over which is placed a perpendicular tube *b*; within this is contained a second tube of considerably smaller diameter, and the space between is filled with sand in order to preserve the temperature of the inner one. This again communicates with the worm of the tub *c*, and terminates in the bottle attached at *d*. The quantity of alcohol contained in the lamp having been accurately determined, flame is applied, and the vapour formed during the combustion of the spirit, passing through the tube *a* becomes condensed in the worm, and in that state is received in the bottle *e*. Lavoisier adds, that by a careful attention to keeping water in the condensing tub always cold, we may obtain 17 ounces of water from the combustion of 16 ounces of alcohol.

The flame of alcohol acquires a red colour from muriate of lime, a deep blood-red from the muriate of strontites, and a green tinge from boracic acid.

Alcohol is a fluid which is remarkably expansible by heat. Dividing the scale between the freezing and boiling points of water into two equal parts, M. De Luc has stated that alcohol expands 35 parts for the first 90°, and 45 parts for the second 90°. The strength of his alcohol, however, is described only by the indefinite test of its firing gunpowder. Mr. Dalton found that 1000 parts of alcohol of the specific gravity .817 at 50° Fahrenheit become 1079 parts at 170°. At 110°, half way between the two extremes, the alcohol was at 1039, or half a division below the true mean. The more the alcohol is diluted with water, the greater he found the disproportion between the two parts of the scale. When of the specific gravity .967, answering to 75 per cent. water, the ratio of expansion through the first half between 50° and 170°, was to that through the second half as 35 to 45, which is precisely the same as De Luc gives for pure alcohol. In reporting these results no account is taken of the expansion of the glass vessel, and consequently the real expansions may be considered as rather exceeding the apparent ones which have been stated.

Alcohol boils at 176°. If water be added, its boiling point is proportionably raised; so that the temperature at which it boils, is not a bad test for its strength. At this degree of heat, it is converted into a vapour, which may be exploded by passing an electric spark through a mixture of it with oxygen gas.

Alcohol of the specific gravity .8152 at 50° Faht., gives a gas, the density of which is 1½ times that of the atmosphere. To become gaseous, alcohol absorbs 0.436, the caloric required to vaporize an equal weight of water.

It has never yet been congealed by any known method of producing artificial cold. Even when diluted with an equal weight of water, it requires a cold of 6° below 0 to congeal it. Mr. Hutton has given in the *Edinburgh Encyclopædia*, under the article *Cold*, an account of his having succeeded several years since in solidifying alcohol by a cold of —110°, but the process by which he accomplished it has not yet been published. The alcohol he employed had a density of .798 at 60°.

Alcohol is a powerful solvent. It dissolves soap; vegetable extract; sugar; oxalic, camphoric, tartaric, gallic, and benzoic acids; volatile oils; resins; and

balsams. It combines also with sulphur, phosphorus, and the pure alkalies; but not with their carbonates. Of the class of salts with alkaline, earthy, and metallic bases, alcohol dissolves some copiously, others sparingly, and others not at all. The proportion in which some of these are taken up, is stated in the following Table by Wenzel, the principal defect of which is the omission of the specific gravity of the alcohol employed.

Two hundred and forty grains of boiling alcohol dissolve of

	Grains.
Borate of ammonia	1
Fluate of alumine	1
——— ammonia	1
Muriate of ammonia	17
——— lime	288
——— magnesia	1313
——— potash	5
Nitrate of alumine	240
——— ammonia	214
——— lime	288
——— magnesia	694
——— potash	5
——— soda	23
Oxalate of alumine	7
Tartrate of alumine	7
——— ammonia	7
——— potash	1
Super-tartrate of potash	7
——— oxalate of potash	7

Mr. Kirwan, also, has given us a very useful Table, showing the power of alcohol at different specific gravities to dissolve several of the neutral salts. The salts were first deprived of their water of crystallization, and were digested, during three days, with alcohol, the temperature of which never exceeded 80° Fahrenheit.

	100 grains of alcohol at				
	.900	.872	.848	.834	.817
Sulphate of soda	0	0	0	0	0
——— magnesia	1	1	0	0	0
Nitrate of potash	2.76	1	0	0	0
——— soda	10.5	6	...	0.38	0
Muriate of potash	4.62	1.66	...	0.38	0
——— soda	5.8	3.67	...	0.5	
——— ammonia	7.5*	4.75	...	1.5	
——— magnesia	21.25	...	23.75	36.25	50
——— barytes		...	0.29	0.18	0.09
crystallized	1.56	...	0.43	0.32	0.06
Acetate of lime	2.4	...	4.12	4.75	4.88

Some salts, also, when actually dissolved in water, are precipitated by the addition of alcohol. This is the case chiefly with the sulphates, several of which are precipitated immediatley, while others are not separated without the application of heat and a few days' repose.

Alcohol, when transmitted through a red-hot copper tube, is decomposed. The tube is found lined with a very fine light soot resembling lamp-black, and an enormous quantity of carburetted hydrogen gas is evolved, not less, as appears from an experiment of Van Marum, than ten cubic feet by the decomposition of three ounces of alcohol. From the analysis of this gas, Mr. Cruickshank has inferred that in alcohol the carbon is to the hydrogen in the proportion of 4 to 1.*

* Nicholson's Journal, v. 7.

In order to determine accurately the composition of alcohol, Lavoisier burned a quantity with very minute attention to the products. The weight of alcohol consumed amounted to 93.5 grains, and 110.32 grains of oxygen were expended in the combustion. The water produced amounted to 106.2 grains, and the carbonic acid to 93.8. From the known quantity of carbon in carbonic acid, and of hydrogen in water, Lavoisier inferred that the alcohol, on which he operated, consisted of

Carbon	28.53
Hydrogen	7.87
Water (existing in the alcohol)	63.6
	100.00

Comparing, then, the composition of alcohol with that of sugar (a compound, as has already been stated, of 8 parts hydrogen, 64 oxygen, and 28 carbon), the same distinguished philosopher was led to the conclusion that, during the vinous fermentation, part of the carbon, by uniting with the oxygen, passes to the state of carbonic acid, and that the remaining carbon, with the hydrogen of the sugar, composes alcohol. If, therefore, it were possible to combine carbonic acid and alcohol, sugar ought to be regenerated.

An analysis of alcohol has been executed with considerable skill by M. de Saussure, by passing the vapour of alcohol at 62° and of the specific gravity of .830 through a red-hot narrow porcelain tube which communicated with a glass one about six feet in length, and refrigerated by ice. A gas was produced, which on analysis resolved itself into carbonic acid and water; and the alcohol was thus proved to contain

Carbon	51.98
Oxygen	34.32
Hydrogen	13.70
	100.00

Beside the hydrogen necessary to form water with the 34.32 parts of oxygen, there are 9.15 parts of hydrogen in excess. Now it is remarkable that this excess of hydrogen is to the carbon in alcohol (51.98) in the same proportions as the hydrogen is to the charcoal of olefiant gas; and we are, therefore, entitled to consider 100 parts of alcohol, of specific gravity .792, as constituted of (9.15 + 51.98 =) 61.13 parts of olefiant gas and 38.87 of water; or of two atoms of olefiant gas, and one of water; or of two atoms of charcoal, three of hydrogen, and one of oxygen.

In 100 parts of alcohol, specific gravity .792, we have, therefore, the elements of 100 parts of olefiant gas, united with those of 63.6 water. But as this alcohol may still be supposed to contain 8.3 per cent. water, real alcohol is probably constituted of 100 parts of the elements of olefiant gas, and of 50 parts of water.

By distillation with the more powerful acids, alcohol undergoes an important change. It is converted into a liquid considerably lighter than alcohol, and much more volatile and inflammable, and miscible only in small proportion with water. This fluid has received the generic name of *ether;* and the peculiar varieties are distinguished by adding the name of the acid, by the intervention of which they have been prepared.

Table of the quantity of alcohol, of specific gravity .825 at 60° Fah. in various Wines, &c.

Vin de Grave	12.80		

Some doubt may, perhaps, be excited of the accuracy of this table, by a reference to the comparative intoxicating effects of port wine and brandy, the latter of which certainly are more than double those of the former. But it is to be remembered, that, in wine, the alcohol is in a state of combination with other ingredients, which must necessarily diminish its activity on the animal system.

The above very interesting particulars are chiefly from the scientific pages of Dr. Henry.

While speaking of alcohol, we must not omit to point out a new process for procuring it which is now carried on to a considerable extent in the metropolis. It has long been known that alcohol must of necessity be liberated during the fermentation of bread, but it was left to the persevering researches of the present period to turn this scientific fact to beneficial account. Large bakeries have lately been erected for the purpose of manufacturing bread and collecting the spirit which is thus produced; and this is effected by the use of a close oven, and refrigeratory, somewhat similar to the ordinary process of distillation.

Alcove, in *Architecture;* the recess or part of a chamber which was formerly used in most civilized countries as a dormitory. The word is derived from the Spanish alcoba, which, according to the older dictionaries of that language, signifies a vaulted cabinet in a chamber, open on one side, without windows, and large enough to contain a bed. The Spanish word is derived from the Arabic al kubbeh, the alcove, the place for the bed, and alkubbeh is probably from alkubbaun the tent, or more probably from khaub, sleep, alkhaub, the bed, alkaab, the cave. The relation of these words is curious. According to the Spanish description, an alcove is not unlike a cave or recess in a rock, in which a wandering Arab might make his abode for the night.

Alcoves in ordinary rooms are square recesses, conformable to the definition we have given, and are finished in a style corresponding with the apartments to which they belong, and with flat or vaulted ceilings as taste may direct, or the height of the alcove may require: but in chambers of greater magnificence, and rooms of parade, they are not always recesses; but more properly a portion of a large apartment separated from the rest by an arch, or balustrade, a screen of columns, or some other decorations, and elevated a few steps above the general level of the floor. On this elevated platform a state bed is usually placed, and sometimes seats and sofas to entertain company. This is what the French architects denominate an alcove. The recess to which the English have appropriated the term, and which is conformable to its primary signification, the French denominate a niche, as may be seen in *Blondel de la Decoration des Edifices en general.*

The authors of the *Encyclopédie Méthodique* are of opinion, that alcoves were in use among the ancients, and this would be indisputably true if we could receive the term in the lax sense in which they have explained it. But we cannot give the name of alcoves to the enclosures which they mention, consisting of a kind of moveable balustrade hung round with drapery, and placed in any part of a chamber at pleasure; nor to those draperies supported by terms, or affixed to the wall, which frequently occur in antique basso-relievos. It must be confessed, that we know very little of the private apartments of the ancients; yet, if a recess for the bed to stand in had been a fashionable feature in a Greek or Roman bed-chamber, it is probable that it would have been mentioned by Vitruvius or others, and especially by Pliny, who is so minute and particular in the description of his Laurentine and Tusculan villas. In each of these villas he describes a small elegant retired closet, furnished with a bed, which by means of glass folding-doors and curtains, could be occasionally laid into or separated from the adjoining apartment. These closets appear to have been somewhat similar to alcoves, but they differ essentially from modern alcoves in having windows.

Ale. A fermented liquor, obtained from an infusion of malt and hops. This liquor, the natural substitute of wine in such countries as could not produce the grape, was originally made in Egypt, the first planted kingdom on the dispersion from the east, that was supposed unable to produce grapes. And as the Noachin colonies pierced farther into the west, they found, or thought they found, the same defect, and supplied it in the same manner. Thus the nations of Spain, the inhabitants of France, and the aborigines of Britain, all used an infusion of barley for their ordinary liquor; and it was called by the various names of *cælia* and *ceria* in the first country, *cerevisia* in the second, and *curmi* in the last; all literally importing *strong water.*

"All the several nations (says Pliny) who inhabit the west of Europe, have a liquor with which they intoxicate themselves, made of corn and water. The manner of making this liquor is somewhat different in Gaul, Spain, and other countries, and is called by many various names, but its nature and properties are every where the same. The people of Spain, in particular, brew this liquor so well, that it will keep good a long time. So exquisite is the cunning of mankind in gratifying their vicious appetites, that

they have thus invented a method to make water itself intoxicate." The method in which the ancient Britons, and other Celtic nations, made their ale, is thus described by Isidorus and Orosius: "The grain is steeped in water and made to germinate, by which its spirits are excited and set at liberty; it is then dried and grinded; after which it is infused in a certain quantity of water; which being fermented becomes a pleasant, warming, strengthening, and intoxicating liquor." This ale was most commonly made of barley; but sometimes of wheat, oats, and millet.

Anciently the Welsh and Scots had also two kinds of ale, called *common ale* and *spiced ale;* and their value was thus ascertained by law: "If a farmer hath no mead, he shall pay two casks of spiced ale, or four casks of common ale, for one cask of mead." By this law, a cask of spiced ale, 9 palms in height, and 18 palms in diameter, was valued at a sum of money equal in efficacy to 7*l.* 10*s.* of our present money, and a cask of common ale, of the same dimensions, at a sum equal to 3*l.* 15*s.* This is a sufficient proof that even common ale in this period was an article of luxury among the Welsh, which could only be obtained by the great and opulent. Wine seems to have been quite unknown even to the kings of Wales in this period, as it is not so much as once mentioned in their laws; though Giraldus Cambrensis, who flourished about a century after the conquest, acquaints us that there was a vineyard in his time at Maenarper, near Pembroke, in South Wales.

Ale was the favourite liquor of the Anglo-Saxons and Danes, as it had been of their ancestors the ancient Germans. Before their conversion to Christianity, they believed that drinking large and frequent draughts of ale was one of the chief felicities which those heroes enjoyed who were admitted into the hall of Odin.

There are various sorts of ale known in Britain, particularly *pale* and *brown;* the former is brewed from malt slightly dried, and is esteemed more viscid than the latter, which is made from malt more highly dried or roasted.

In order to make a strong keeping ale of an excellent quality, the following should be the proportion of the ingredients: forty bushels of best pale malt and fifty pounds of hops. For the first mash, ten barrels of water at 172° may be let on and raked for half an hour, and then allowed to stand for an hour. Water at 180° may then be leaked or let on so as to run through the malt, and to wash away all the wort soaked in the previous mash. These two liquors, when boiled down with the hops, fermented, and finished, ought to produce eight barrels of ale at 100 pounds' gravity on Dicas's saccharometer. But in the one mash the malt is by no means exhausted of its saccharine matter, although what remains is not of so fine a quality as that which had been dissolved away. The same malt and hops will, however, answer extremely well for making table-beer; and with this intent a second mashing may be made with water of 185°, and even a third with water of 190°; the quantities being such, that after boiling on the same hops, fermenting, and finishing, there will be twelve barrels of beer at thirty pounds' gravity.

An inferior, but yet a good ale may be made from forty bushels of prime pale malt, and thirty pounds of good hops. The mashing heat may be as before, and it may be calculated as before to produce both ale and beer. In this case, twelve barrels of ale at seventy pounds' gravity, and ten barrels of beer at thirty pounds will be produced. Or, if the object is merely to obtain ale at seventy pounds' gravity, the quantity producible will be fourteen barrels. If table-beer of a good quality, without any ale, is required, the quantity of materials to produce thirty barrels of finished beer should be, malt forty bushels, good hops twenty-five pounds, as much water as will produce thirty-five barrels of hopped wort; and this will finish about thirty barrels of beer. In calculating the quantity of water necessary to produce a given quantity of a first mash, it will be of use to know that an imperial bushel of ground malt absorbs and retains about 6¼ imperial gallons of water.

The Burton ale having attained a very high character for its strength and flavour, it may be advisable to point out the process by which it is prepared. It is made from the palest malt and hops; for, if it be not pale as straw, it will not pass with the connoisseurs in that article; and the gravity being so very high as thirty-six to forty pounds a barrel, makes it a matter of great nicety to get malt sufficiently pale.

If the malt be not very good, only one mash must be made for this liquor; but if it be good, two mashes may take place, adverting still to the great specific gravity which ought to be produced.

The heat of the liquor should be 185°, or 190°, adding 5° for the second mash.

If only one wort be made, it may be boiled an hour and a quarter; if two, they may be boiled three-quarters of an hour the first, and an hour, or an hour and a quarter the second; remembering that long boiling is prejudicial to the colour.

The quantity of hops must be three-quarters of a pound per bushel of malt, or more, according to circumstances; but the more that are used, though an advantage as a preservative, the higher will be the colour of the ale.

The heat of fermentation should not much exceed 75°, and as the first heat would thence probably be about 55°, the quantity of yeast, both on account of this circumstance, and the great weight of the wort, should not be less than three pounds per barrel, used as is before recommended; and the rule for cleansing is the same as that before inculcated.

It is to be racked into clean casks (without hops) when nearly pure, and the sizes of them are from 32 to 42 or 43 gallons (called *half hogsheads*), and from 70 to 80 gallons (called *hogsheads*), which are generally hooped with an equal number of iron and wooden hoops; the latter are white, flat, or broad bark hoops; a bar is put across each head, and the brewer's initials or name, with B, or Burton at length, are branded in front in letters of about an inch and a quarter high; and the number of gallons which the casks holds is cut with a scribe-iron, just above the cork-hole.

The bung-hole is not above an inch and a quarter in diameter, which is stopped with a wooden shive or bung, and a piece of triangular tin-plate is afterwards nailed over it. See Beer and Porter.

Alembic. This is a very useful chemical instrument, and is used for distillation, when products are of too volatile a nature for the use of the retort. It is indeed a sort of matrass with a capacious head fitted to it, and from the head proceeds a tube or beak, like the neck of a retort. As the external circumference or base of the head is lower than the beak, the vapours which rise and are condensed against its

sides, first run down into the channel formed by the depressed part, and thence are conveyed off by the beak. The alembic is a more complex instrument than the simple retort, which with care will answer as well, except, perhaps, for those bodies which are partly vapourized, and partly sublimed; in which case the sublimed part is very conveniently retained by the head.

Algebra, is that part of mathematics in which symbols are employed for the purpose of abridging and generalizing the reasonings which occur in the solution of questions relative to numbers. By some writers it is used synonimously with analysis, but there is this distinction between the two, that algebra is the science which relates to the calculation of magnitudes in general, and analysis, the method of resolving mathematical poblems by the aid of algebra.

The earliest treatise on Algebra which has been transmitted to the present times, is that of Diophantus of Alexandria, who flourished about the middle of the fourth century of the Christian era. It consisted of thirteen books, the first six of which only are now extant. They were printed in the form of a Latin translation, by Xylander, in 1575, and afterwards in Greek and Latin, with a commentary by Bachet, in 1621; and subsequently, in 1670, with corrections and marginal annotations by Fermat. The investigations contained in these do not extend beyond quadratic equations, and the expression is that of common language assisted by a few symbols. Notwithstanding that this is the earliest production we possess on this subject, there are strong reasons for believing that algebra, as well as our ordinary system of notation, originated with the Hindus; who have been found to possess some valuable works of this nature, containing rules and principles that do not appear to have been derived from any foreign source. The chief of these performances are the *Cuttaca d'haya*, and the *Ganita d'haya* of Brahmagupta, a Hindu astronomer and mathematician who flourished about the latter end of the sixth century, and the *Bija Ganita* and *Lilavati* of Bhascara *Acharya*, another astronomer of the same nation, who lived about the year 1150. From this latter work, it appears that besides a knowledge of most of the common rules of algebra, the Hindus were at that period acquainted with some branches of the science which were not known in Europe till the latter end of the seventeenth, and middle of the eighteenth century.

Europe, however, owes its first acquaintance with this science to the Arabians, from whom, through the medium of commerce, it was introduced into Italy early in the thirteenth century, by Leonardo Bonacci, a merchant of Pisa, two of whose manuscripts, dated 1202, and 1228, are mentioned by Cossali. Many manuscript writings of a similar nature to these appeared soon afterwards in various parts of Italy; but the first printed works on the subject are those of Lucas Paciolus, de Burgo Santi Sepulchri, whose principal production is that entitled *Summa Arithmeticæ et Geometricæ, Proportionumque et Proportionalium*, which was published in 1469. From this performance, which exhibits the state of the science towards the latter end of the fifteenth century, it appears that the earlier European analysts, as well as those of Arabia, used no symbols or signs to represent either quantities or the operations that it was necessary to perform on them, with the exception of a few verbal abbreviations. The letters *p* and *m* were used to denote plus and minus; and it is laid down as a rule to be observed in multiplication, that *plus* into *minus* gives *minus*, but *minus* into *minus* gives *plus*. Thus the first appearance of algebra is merely that of a system of short-hand writing, or a contraction of common language applied to the solution of arithmetical problems.

Soon after the publication of the work last mentioned, and about the year 1505, Ferrei, a professor of Bologna, discovered a method of solving one of the cases of a compound cubic equation. Ferrei was followed by the famous Cardan, who extended his rule, for a particular case, to all the forms and varieties of cubic equations, whether complete or incomplete, and also possessed an acquaintance with the number and nature of their roots, both positive and negative, possible and impossible, or imaginary. The resolution of equations of the third degree was followed close by that of biquadratic equations, or those of the fourth degree, which was discovered by Louis Ferrari, one of the pupils of Cardan. About the same period, the study of the science of algebra was prosecuted in Germany with vigour, particularly by Stifel and Scheubel, the former of whom, in his *Arithmetica Integra*, frequently employs letters to represent numbers, and was the first to introduce the symbols $\times$, —, and $\surd$, to express addition, subtraction, and extraction of a root; but neither this writer nor Scheubel, who published his work in 1552, speak of cubic equations, which were, however, fully treated of by Peter Roth, another German mathematician of that age. In the year 1557, appeared *The Whetstone of Witte, which is the seconde parte of Arithmeticke, containing the Extraction of Rootes, the Cossike Practice, with the Rules of Equations, and the Woorkes of Surde Nombers*," by Robert Recorde, a native of Wales. This treatise contains a method of extracting the roots of compound algebraical quantities; and it is the first in which we meet with the use of the sign $=$ to represent equality. The several works of Pelletier, Peter Nunez, Bombelli, and Stevin, published at the latter end of the sixteenth and beginning of the seventeenth century, are abundant proofs of the zealous cultivation of algebra in their respective countries of France, Portugal, Italy, and Flanders; but it is chiefly to the celebrated Vieta, master of requests under Margaret of France, that we must attribute its subsequent rapid progress, in consequence of the improvements which he introduced into the system of notation by the employment of the capital letters of the alphabet to denote all kinds of quantities, whether known or unknown, the former being designated by consonants and the latter by vowels. This illustrious man also invented new demonstrations of the rule for resolving cubic, and even biquadratic equations, and partly discovered the general relation between the roots of those of any degree and the co-efficients of their terms, provided all those roots be real or positive, and none of the terms be wanting. Vieta was followed by Albert Girard, who greatly extended the partial discovery of the former, of the successive formation of the co-efficients of an equation from the sum, of its roots, and the sum of their products, whether they be positive or negative. Among the most eminent analysts of this period we must not omit our celebrated countryman Thomas Harriot, who introduced the use of the small letters of the alphabet instead of the capitals employed by Vieta, and who, by a slight improvement which he made in algebraical

language, laid the foundation of the most important branches of that science. We allude to the method of writing an equation in the form of $x^2+ax-b=o$ instead of $x^2+ax=b$.

By this succession of discoveries the algebraic analysis was prepared for the step about to be taken by Descartes, and which forms one of the most important epochs in the history of the mathematical sciences. This was its application to define the nature and investigate the properties of curve lines, and consequently to represent the notion of variable quantity.

Although undoubtedly previous to the time of this distinguished philosopher great progress had been made in researches purely algebraical, yet the notation in use was exceedingly imperfect, and encumbered with ideas of actual relation to magnitude which inseparably connected every algebraic quantity with notions of extension and solidity. The principal object and utility of algebra is, however, to express purely and without reference to any particular values which may be assigned to them, the abstract relations of quantities. That this object might be attained, it was absolutely necessary to disentangle the science from all those extraneous considerations which limited its application and extension. This was the first service rendered to algebra by Descartes; and the metaphysical character of this illustrious man's genius was of singular utility to him in the performance of it. According to the method of notation then in vogue, the product of any quantity multiplied by itself once, was indicated by annexing to that quantity the geometrical figure called the square; and that of a quantity multiplied by itself twice, by a delineation in perspective of the solid known by the name of the cube. These operations were also denoted respectively by the letters Q and C placed above the quantity to be multiplied, and sometimes by a mere repetition of the letter which designated that quantity the same number of times that it was to be made a factor; in other words, according to the ordinary mode of expressing multiplication. In the place of this embarrassing notation which fettered and impeded the exercise of thought on the subjects which it was intended to enlighten, Descartes substituted one, clear, simple, and general. Instead of the letters Q and C, which were simply verbal abbreviations, he placed above the quantity to be multiplied the figure which denoted the number of times which the operation of multiplication was to be performed, or its *power*. The great value of this important alteration will be fully appreciated by a simple inspection of some of the algebraical expressions which occur in the writers on this subject who preceded Descartes, and by a comparison of their complicated confusion with the simplicity and perspicuity which they assume from the introduction of exponents. By means of this and other improvements, the leading principles of algebra were more thoroughly unfolded, and the notation was converted from a mere collection of abbreviated forms of common language, into a system of symbolical writing capable of being applied with the greatest advantage to aid the operations of the mind.

We have now rapidly traced the science of algebraic analysis from its origin and early form, to the period when it attained a degree of perfection little short of that which it has reached at the present day. Succeeding authors are too numerous, and with a few bright exceptions, their improvements too inconsiderable to merit any minute mention. To Newton we are indebted, amongst other things, for his well known demonstration of the *Binomial Theorem*; and his *Reversion of Series*, or method of finding the value of the root of an infinite series, in terms of another series of a different kind; both of which inventions are rendered universal by means of the general exponent which he first introduced into analytical operations. The zealous labour bestowed on the theory of series during the last two centuries, has also been productive of great advantage to this science, and the researches of the Bernoullis, Taylor, Demoivre, Stirling, Euler, and Leibnitz, have greatly improved and extended that important branch of algebraic analysis.

NOTATION.

The object of algebra is, as we have before observed, to assist the operations of the mind in the consideration of questions relative to number. The method in which this object is attained, and the utility of that method, may be best shown by reference to a question of that nature. Let it be proposed

To divide a given number into two parts, such that one shall be greater than the other by a given excess.

By the conditions of the question,

1°. *The greater of the two parts is equal to the lesser increased by the given excess.*

Therefore if the lesser be known by adding to it the excess, we shall obtain the greater.

2°. *The greater part added to the lesser makes up the whole number.* Substituting in this last sentence, in the place of the expression *the greater part*, the equivalent to it in 1°, we find that

The lesser part increased by the given excess, added to the lesser part, makes up the whole number. But the lesser part added to the lesser part, is the lesser part taken twice; therefore,

Twice the lesser part increased by the given excess make up the whole number. Or the given excess must be added to twice the lesser part in order to make up the whole number; but if twice the lesser part *with* the given excess be *equal to* the whole number, *without* the excess it will be *less than* that number by so much as the excess; or

Twice the lesser part is equal to the whole number diminished by the given excess. Therefore,

The lesser part is equal to the half of the difference between the whole number and the given excess.

From this last sentence we perceive, that to obtain the lesser of the two required parts, it is only necessary to perform simple arithmetical operations on the whole number and the given excess, both of which are known. Thus, if the number to be divided be 14, and the excess of the one of the parts into which it is to be divided above the other, 6, the lesser part will be equal to the half of, 14 diminished by 6, which is 4; and the greater which is equal to the whole diminished by the lesser, will be 10.

We observe that, in the reasonings by which we have been enabled to obtain the above conclusion, several expressions, such as *added to, diminished by, is equal to*, &c. occur repeatedly; it is evident, therefore, that, if instead of writing those expressions, we employed a symbol to represent each of them whenever it occurred, a very material abridgement would ensue. It is on this account that various symbols are used in algebra; each of which serves to indicate that a certain operation is to be performed on the quantities to which it is attached.

The sign +, which is read *plus*, and is termed the

sign of addition, or the positive sign, indicates, the addition of the quantities before which it is placed to some other. Thus $15+28$ is 15 *plus* 28, or 15 increased by 28.

The sign —, which is read *minus*, and called the sign of subtraction, or the negative sign, serves to denote the subtraction of the quantity to which it is prefixed from some other. Thus $32-18$ is 32 *minus* 18, or 32 diminished by 18.

The sign $\times$ is used for multiplication, and has the same signification with a point placed between the quantities to be multiplied. Thus 22×58 or 22.58 is 22 multiplied by 58, and represents the product of 22 by 58, both of which are termed the factors of that product.

The sign $\div$ indicates division, which is however more generally represented by writing the divisor below the dividend with a horizontal stroke between them; thus $6 \div 3$ or $\frac{6}{3}$ means that 6 is to be divided by 3.

When two quantities are equal to one another, their relation is denoted by $=$ placed between them. Thus $8=4+4$ means that 8 *is equal to* $4+4$, and is termed an equation.

When two numbers are unequal, their relation is expressed by the sign of inequality $\angle$ or 7, the open part of the symbol being always turned towards the greater number. Thus $20 \; 7 \; 13$, means that 20 is greater than 13, and $10 \angle 13$, that 10 is less than 13.

By the substitution of these signs, whenever the operations which they represent are to be indicated, in the place of directions to the same effect expressed in ordinary language, our reasonings in regard to quantities and the operations to be performed on them must be greatly simplified. Thus, if we wish to denote that a certain quantity is to be added to another, and that from their sum a third quantity is to be subtracted, we have only to write, first quantity + second quantity + third quantity. But it is obvious that even this abridged form is susceptible of still further abridgment by substituting for first, second, and third quantity, any symbols which we shall agree to stand respectively for those terms; as for instance, three of the letters of the alphabet.

We may thus concisely express the above proposition by $a+b+c$, having previously agreed that in this particular case a shall represent what we have termed first quantity, b second quantity, and c third quantity.

The great advantage of this mode of expression is that the most complicated reasonings are at once presented in a very simple form; so that the mind being enabled to comprehend them as it were at a glance, is at liberty to direct all its energies to the solution of the question which is their object.

We may illustrate this by recurring to the question with which we commenced, namely, that in which it is required to divide a given number into two parts, such that one shall be greater than the other by a given excess, and deducing the same conclusion as then, through the same reasoning, expressed however by means of the system of representative symbols which we have just unfolded.

Let a represent the given number to be divided, b the given excess, and x the lesser of the two parts into which it is required to divide a; then $x+b$ will represent the greater. By the conditions of the question,

$$x+x+b=a$$

$$\text{Or } 2x+b=a$$

$$\text{Therefore } \quad 2x=a-b$$

$$\text{And } \quad x=\frac{a-b}{2}$$

$$\text{Or } \quad =\frac{a}{2}-\frac{b}{2}$$

Having thus found the lesser part, we may easily obtain the greater, which is represented by $x+b$, and which, therefore, $=\frac{a}{2}-\frac{b}{2}+b$, or $\frac{a}{2}$ diminished by one half of b, and increased by the whole of b, which is

$$\frac{a}{2}+\frac{b}{2}$$

The correctness of our operation we may test by adding together the results obtained for the two parts, which, according to the conditions should be equal to the whole number to be divided. Thus, $\frac{a}{2}-\frac{b}{2}$ added to $\frac{a}{2}+\frac{b}{2}$, is the half of a added to the half of a, or the whole of a, first diminished and then increased by the half of b, two operations, the latter of which neutralizes the former, and which consequently have no effect on a, which remains the sum of the addition. Hence our results fulfil the conditions required, and are therefore correct. The student may observe that we have represented the whole number and the given excess by a and b, and the part which it is required to find by x. In so doing, we have only conformed to a long-established and highly convenient usage, that of designating all the known quantities in an expression by the early letters of the alphabet, and the unknown by the concluding ones. By this arrangement we are enabled, in collecting on the opposite sides of an equation the different terms composing these two classes, immediately to distinguish to which any quantity belongs.

In addition however to the abridgement effected by the ordinary method of employing representative symbols for the purpose of indicating the performance of certain operations, a variety of abbreviations occur in the application of that method, especially to quantities designated by letters.

Thus, when numbers represented by letters are to be multiplied together, the ordinary signs of multiplication may be dispensed with, and the operation will be equally indicated by writing the letters in succession one after the other. Thus, $a\,b$ has the same signification as $a \times b$, or $a.b$, and abc, the same as $a \times b \times c$, or $a.b.c$. This mode of expression must evidently be confined to letters; for in the common system of notation, a very different meaning is attached to a similar arrangement of figures. Thus, 8×4, or 8 multiplied by 4, if written 84, would be confounded with the number *eighty-four*.

When a number designated by a letter is to be added to itself several times, the letter is written only once, and before it is placed the figure which marks how many times it occurs, and which is termed its *co-efficient*. Thus, instead of $x+x+x+x+x+x$, we write $6x$, when we wish to express that x is to be added together six times; and 6 is the co-efficient of x.

When a similar quantity is to be multiplied by

itself several times, in this case also the letter is written only once, and above it to the right is placed the number which denotes how often it is a factor, and which is termed its *index*, or *exponent*. Thus, $a \times a$, or $a\,a$, is written a^2, and is called the *square*, or *second power* of a; $a \times a \times a$, or aaa, a^3, and is termed the *cube*, or *third power* of a; $a \times a \times a \times a$, or $aaaa$, is denoted by a^4, and is the *fourth power* of a; and a^n is the n^{th} power, and represents a quantity composed of the factor a occurring n times, whatever number n may represent.

In connection with the raising of powers is another operation directly the reverse, called the extraction of roots. The *root* of any quantity is another quantity, which, multiplied by itself a certain number of times according to the denomination of that root, produces the first quantity. Thus, the *square root*, or, as it might more properly be termed, the *second root* of a, is a quantity, which, multiplied by itself once, or raised to its square or second power, will produce a; the *cube root* or *third root* of a, is a quantity which, when multiplied by itself twice, or raised to its cube or third power, will give a; and the fourth root of a is one, which when multiplied by itself three times, or raised to its fourth power, will also produce a. The operation of extracting a root of any quantity is denoted by prefixing to that quantity the *radical sign* $\surd$, and writing above it the number denoting the power or degree of the root to be extracted. The square root of a is expressed by $\sqrt[2]{a}$, or more simply by $\sqrt{a}$, the cube root by $\sqrt[3]{a}$, the fourth root by $\sqrt[4]{a}$, and the n^{th} root by $\sqrt[n]{a}$.

It is particularity necessary for the beginner thoroughly to understand the distinction between such expressions as $3a$, and a^3, as from an insufficient attention to this point arise much perplexity and confusion. He should remember the operations by which each of them respectively is obtained; that $3a$ represents the addition of a three times, and a^3 the multiplication of a three times; that in the latter case the number 3 is an *exponent*, in the former, merely a *co-efficient*. The difference will become still more apparent by writing out a few such expressions at full length, as in the following examples:

$$\begin{aligned}
a^2 &= a \times a \\
2a &= a + a \\
a^3 \times b^2 &= a \times a \times a + b \times b \\
3a + 2b &= a + a + a + b + b \\
a^6 &= a \times a \times a \times a \times a \times a \\
6a &= a + a + a + a + a + a
\end{aligned}$$

We now proceed to explain the mode of effecting the ordinary operations of arithmetic upon algebraic quantities or numbers represented by letters, prefixing however a few preliminary definitions and observations.

DEFINITIONS.

Every collection of numbers written in the language of algebra is termed an expression. Thus, $x + y$ is the algebraical expression for the sum of the numbers x and y; and $3x - 8y + 42$ is the algebraical expression for the number x taken three times, diminished by y taken eight times, and increased by z taken four times.

The different portions of which an expression is composed, and which are connected together by means of the signs $\times$ and $-$, are called the *terms* of that expression. Thus $3x$, $8y$, and $4z$, are the terms of $3x - 8y + 4z$.

Quantities may consist of one or more terms; in the former case, they are called *monomials*, or simply *terms;* in the latter, they are designated by the general appellation of *polynomials*. They are also called *binomials* when the number of terms is two, and *trinomials* when three.

When we wish to indicate that any operation is to be performed on a quantity consisting of more than a single term, it is necessary to enclose that quantity in brackets, or draw a line over it. Thus $(a + b)\ (c + d)$ or $\overline{a + b}.\ \overline{c + d}$, means that the sum of a and b is to be multiplied by the sum of c and d; and is thus written in order to distinguish it from $a + b.\ c + d$, which means simply that to a is to be added the product of b and c, and that the sum is to be increased by d. Again, $a - (b - c)$ means that from a is to be taken b, diminished by c; $a - b - c$ would signify that both b and c were to be subtracted instead of merely their difference being so. An attention to this point is also indispensable, in indicating the operation of raising powers; as for instance, $(a + b)^3$ denotes that the sum of a and b is to be multiplied by itself twice; while $a + b^3$ merely implies that b singly is to be multiplied by itself that number of times, and the product added to a.

The numerical value of an algebraical expression is the number which would result from the performance of all the operations indicated in that expression, were particular values assigned to the different letters contained in it; and generally varies with those values. Thus the numerical value of $4a^2$ is 16 when $a = 2$; 36 when $a = 3$; and 64 when $a = 4$.

The numerical value of a polynomial is not changed by altering the order of its terms, provided the particular sign of each be retained. For instance, $a + b$ means that b is to be added to a, and $b + a$, that a is to be added to b; but the results of these two additions are evidently the same; therefore, if for the one expression we substitute the other, we do not affect its value. Similarly, $3a + b - 4c$, may be written $b + 3a - 4c$, or $b - 4c + 3a$, or $3a - 4c + b$, or $-4c + 3a + b$, it being particularly understood in this last expression that $4c$ is considered as to be subtracted from what follows it. It should, however, be well remembered that all these are different expressions, and that the operations indicated in each of them are perfectly distinct; and that we substitute them one for another, not because the operations indicated in each are the same, but because when performed they lead to the same conclusions.

Of the different terms of a polynomial, some are preceded by the sign $+$, some by that of $-$; the former are called *positive* terms or quantities, and the latter *negative* ones. Using these symbols in the signification which we have attached to them, a positive quantity is a quantity to be added, and a negative quantity a quantity to be subtracted. The performance of either of these operations necessarily implies a connection with some other quantity; for we cannot add a quantity unless we have something to which to add it, or subtract one unless we have something from which to subtract it. Hence, according to this definition, an isolated term to which either of the signs $+$ or $-$ is prefixed, such as $+a$ or $-a$, is unintelligible; it directs us to perform upon a single term an operation, to the performance of which two are essential. There is, it may be remarked, an extention of the use of the sign $+$, to which we shall come presently, introduced purely for the sake of

convenience, and which consists in regarding the first term of an expression to which no sign is prefixed, to be as effectually preceded by + for all the purposes of certain operations, as if + actually stood before it; and also a conventional usage of both + and —, in a sense somewhat different from, though analogous to, that conveyed by the ordinary definition; of this latter we shall speak hereafter.

Each of the literal factors composing a term is said to be a *dimension* of that term, and the number of its dimensions determines its *degree*. Thus, $2a$ is a term of one dimension, or of the first degree; $8\,ab$, one of two dimensions, or of the second degree, and $10\,a^2\,b^3\,c^4$, one of nine dimensions, or of the ninth degree, the factor a occurring twice, b three times, and c four times. Similarly, $3\,a^8\,b^6\,c^7\,d^9$ is a term of twenty-four dimensions, or of the twenty-fourth degree; and upon taking a number of terms similar to this and the preceding, in which each of the letters has an exponent attached to it, we should find that generally the degree or number of dimensions of a term may be ascertained by the addition of the exponents of the letters contained in it. But this rule evidently cannot apply to the case of $8ab$, neither of the letters of which has any exponent; but it will apply if we slightly extend our notation of exponents, and represent a and b, as according to analogy they ought to be represented, namely by a^1 and b^1, which we may term *first powers* of a and b. We are thus enabled to comprise under one rule that which would otherwise require two.

Like terms are those which consist of the same letters raised to the same powers, and which differ, if at all, only in their co-efficients; as $2ab$ and $4ab$, $6b^2\,a^3\,b^2$ and $22a^3\,b^2$. When they differ in other respects, they are called *unlike terms*. It frequently happens that several of the terms of a polynomial are alike; in such a case it is capable of being simplified. Thus, $4a + 2ab^2 + 8b - 6ab^2 - 3b + 12ab^2 - 3ab^2 - 2b$, may be written $4a + 2ab^2 + 12ab^2 - 6ab^2 - 3ab^2 + 8b - 3b - 2b$, without altering its value; but ab^2 taken twice, added to ab^2 taken twelve times, is evidently ab^2 taken $2 + 12$, or 14 times; and $14ab^2$ diminished, first by 6 times and then by 3 times ab^2, is the same as $14ab^2$ diminished by 9 times ab^2, which is $5ab^2$. Similarly, 8 times b, diminished by 3 times b and by twice b, is 3 times b; therefore the original polynomial may be reduced to the form of $4a + 5a^2\,b + 3b$. From this and other examples of this sort, we deduce the following rule for the reduction of the like terms of an expression:—Collect into a single term all the like terms preceded by +, by adding together their co-efficients and prefixing the sum as a co-efficient to the literal portion common to all; in a similar manner collect into a single term all the like terms preceded by —; if the co-efficient of the former of the single terms thus obtained be as great as that of the latter, subtract that of the latter from it, and the term obtained by prefixing the difference to the literal portion common to both, will be the lowest reduced form of the given expression; but if the co-efficient of the former of the single terms be not so great as that of the latter, the latter preceded by its sign of subtraction must be written after the former, as an indication of the operation, and the expression thus obtained will be the lowest reduced form.

There are however two cases in which this rule does not apply, namely, when any one of the like terms has no co-efficient, and when any one has no sign. Thus $a + 3a$ is an expression, both the terms of which are like, and which we perceive by writing it at full length is equal to $4a$; but if we reduce it according to the rule, we obtain only $3a$, a result which is too small. The rule is therefore inapplicable to this case, and for this reason, that it proceeds upon the supposition of every term possessing a co-efficient, while from the sense in which we employ that symbol, a letter occurring singly, as a, has none. But it will be rendered applicable, and we shall obtain a correct result if we extend our definition of a co-efficient as we have already extended that of an exponent, and represent a as from analogy it might be represented, namely, by $1a$. We therefore consider a always to stand for $1a$, or rather taking into account our late extension of the meaning of exponent for $1a^1$, although it is simply written a.

The second case in which the rule is inapplicable is when the first term of a polynomial, which has no sign prefixed to it, is one of the like terms. The meaning we have attached to the signs + and — is that of symbols serving to connect one quantity with other quantities, by being prefixed to those others, and to denote that certain arithmetical operations are to be performed on them by means of the first one. But the first quantity being that to which the operations on the others are to be referred, is not considered to be added to, or subtracted from, any previous one, and therefore has no sign placed before it. Our rule embraces only the cases in which every one of the like terms is preceded by a sign; but it may be rendered applicable to those in which none is prefixed to the first term, by supposing that term to be for the purposes of this operation, preceded by +; and the results obtained by proceeding on this supposition will be correct.

ADDITION.

The addition of quantities consisting of a single term is indicated by connecting them with the sign +; thus $a + b$ means that b is to be added to a. We cannot actually perform the operation so indicated, because the letters a and b signify nothing in themselves: we express the sum of 6 and 4 by 10, because each of those numbers possesses a definite meaning, which enables us to say that the idea we attach to their sum is the same with that which we attach to the number 10. But as a and b are indefinite symbols with our ideas of which no particular values are connected, their sum must necessarily be indefinite also, until we assign some value to them. When we write $a + b$ then, we do not actually perform an addition, but rather indicate that that operation is to be performed when values are given to a and b.

Again, $8a^2\,b$, $6a^2b$ and $13\,a^2\,b$ are to be added together; their sum is represented by $8\,a^2b + 6\,a^2b + 13\,a^2b$. This expression we observe is capable of reduction, as it contains like quantities; and the result of that operation is $27\,a^2\,b$.

Hence the addition of monomials consists strictly in merely connecting the quantities to be added by the sign +; the subsequent simplification of the expression so obtained is referred to the operation of reduction.

Let it be required to add the polynomial $c - d$ to that of $a - b$. If we add c to a, we obtain $a + c$; this sum is, however, too much, for it is not a which is to be increased by c, but $a - b$, or a diminished by b; it must therefore be decreased by b, and will become

$a + c - b$; but the result which we have is again too great, because it is not c which is to be added, but $c - d$, or c diminished by d; we must therefore decrease it by d, and it will then become $a + c - b - d$, or $a - b + c - d$. Similar reasonings might be applied to other polynomials, and we may hence deduce this rule for the addition of two or more polynomials. Write the proposed quantities in succession one after the other, preserving to each term its respective sign, and simplify the result by the reduction and collection into one term of all the like quantities.

It is evident that this rule cannot apply to the first term of a polynomial which is to be added, when that term has no sign prefixed to it. Thus, in proceeding to add $c - d$ to $a - b$, according to the rule, we find that c has no sign by which to connect it with that expression. If we look, however, to the result which we obtained, without reference to the rule, we find that c is preceded by the sign $+$. Hence, in order to produce a correct result according to the rule, we must suppose c in the expression $c - d$ to be preceded by $+$. Further examples would give similar results; hence, in order to avoid the necessity of a second rule, to apply specially to the first term when it has no sign, we consider that term to be for the purposes of this operation, preceded by $+$, although that sign is not actually placed before it, as by so doing we are enabled to obtain correct results.

SUBTRACTION.

Let us proceed to subtraction; $4b$ is to be subtracted from $6a$, the result is expressed by $6a - 4b$. Similarly, $11ab^2$ subtracted from $15ab^2$, is $15ab^2 - 11ab^2$, or $4ab^2$.

Again, it is required to subtract the polynomial $a - b$ from c, which operation is indicated by $c - (a - b)$. We must, however, reduce this expression to one polynomial; for that purpose we take a from c, and obtain $c - a$; but we have taken too much from c, for it is not a that is to be subtracted from that quantity, but a diminished by b; the result must therefore be increased by b, in order to restore the excess of what we have taken above what we ought to have taken, and it then becomes $c - a + b$. If the polynomial to be subtracted from c be $a + b$, both a and b are to be subtracted, and the result is $c - a - b$. Or our two results are,

$$c - (a - b) = c - a + b,$$
$$c - (a + b) = c - a - b.$$

From these we observe, that to subtract $a - b$ from c, we have simply written it after that quantity, with this alteration however of prefixing to each of its terms the contrary sign to that which was attached to it in the original form. It is evident that the same result must be obtained in the subtraction of quantities of more than two terms, in short of any polynomials, and hence we derive the following rule: To subtract a polynomial, write it after the quantity from which it is to be subtracted, at the same time changing the sign of every one of its terms from $+$ to $-$, or from $-$ to $+$, and simplify by the reduction of the like quantities.

With regard to that portion of the rule which relates to the changing of signs, it is evident that in order to render it applicable to terms which have no sign at all, we must, as in the case of the operation of addition, consider such terms to be preceded by $+$. By an attention to this point, we shall be enabled to obtain correct results in all cases under the rule we have given.

MULTIPLICATION.

It is proved in arithmetic that the product of two or more numbers is the same whatever be the order in which they are multiplied; therefore if a is to be multiplied by b, it is indifferent whether we write the product ab or ba. This being regarded as a fundamental principle, we proceed to the multiplication of quantities consisting each of a single term, as $6a^2b^3$ and $4ab^2$. The product of these is $6a^2b^3 \times 4ab^2$. Now if we restore each of these terms to its original form, of which the present is merely a representation, the expression becomes $6 \times a \times a \times b \times b \times b \times 4 \times a \times b \times b$. But as the product of these terms is the same whatever be the order in which we multiply them, therefore the expression may be written $6 \times 4 \times a \times a \times a \times b \times b \times b \times b \times b$, or $6 \times 4 \times aaabbbbb$; and as 6×4, or six taken four times, is 24, this last expression is represented by $24a^3b^5$. We observe that the exponent of a in the product is the sum of the exponents of that letter in the two quantities to be multiplied, as is also that of b. Thus a^2 represents aa, which multiplied by a, is aaa, or a^3; b^3 represents bbb, and b^2, bb; whence $b^3 \times b^2$ is $bbbbb$, which is indicated by b^5. Similarly, we find the product of any two powers of the same quantity to be that quantity raised to the power denoted by the sum of the exponents of each factor contained in it. This is expressed generally by $a^m \times a^n = a^{m+n}$, m and n representing any numbers whatsoever. Therefore to multiply two quantities composed of a single term, write down every letter which occurs in either of them, giving to each for exponent the sum of the exponents of that same letter in the two quantities; to this prefix the product of the two co-efficients, and the expression obtained will be the product required.

The advantage of the extension of the notation of exponents and of co-efficients to single factors of a letter, by giving each, unity for index or co-efficient, as in representing a and b by $1a^1$ and $1b^1$, is now apparent. Had we not done so, the above rule would not have been universal.

It is evident that the number of single factors contained in the product of two monomials is equal to the sum of the number of factors contained in each of them; or the number of the dimensions of the product is equal to the sum of the dimensions of the two monomials.

Let us now proceed to the multiplication of quantities consisting of more than a single term, as a and $b + c$. The product of these is $a(b + c)$, composed of two separate expressions, which it may be necessary to reduce to a single one. To effect this, we multiply a by b, and obtain ab; this however is not enough, it is only a taken b, instead of $b + c$, times; we must therefore take it c times more, which gives us ac to be added to ab. The required product is then $ab + ac$. Again, a multiplied by $b - c$, is $a(b - c)$, which indicates that a is to be taken the number of times contained in b diminished by c. If then we take a, b times, or ab, we have taken it too often by c times; it must therefore be subtracted from that product c times, which gives the result $ab - ac$.

Let it now be proposed to multiply $a + b$ by $c + d$. Consider $c + d$ as a single term; and $(a + b)(c + d)$ becomes $a(c + d) + b(c + d)$, which, from what we have just seen, is equal to $(ac + ad) + (bc + bd)$, or

$ac + ad + bc + bd$. Also $(a - b)(c + d)$ becomes $a(c + d) - b(c + d)$, which is equal to $(ac + ad) - (bc + bd)$, or $ac + ad - bc - bd$, according to the rule for subtraction. Similarly $(a + b)(c - d)$, regarding $c - d$ as a single term, becomes $a(c - d) + b(c - d)$, which is $ac - ad + bc - bd$; and $(a - b)(c - d)$ is $a(c - d) - b(c - d)$, which is equal to $(ac - ad) - (bc - bd)$, or $ac - ad - bc + bd$.

In examining the above results, we observe that the following principles regulate the signs to be prefixed to the different terms which they contain.

When each of the two terms which compose any term in the product is preceded by $+$, the sign of that term is also $+$.

When the sign of one of the terms is $+$, and of the other $-$, that of the term which is composed of them is $+$.

When each of the terms is preceded by $-$, the sign of the term which they compose is $+$.

Hence we deduce the following rule for the multiplication of two polynomials: multiply each term of the one by each term of the other, and whenever both of the terms so multiplied have the same sign, prefix $+$ to their product; but when their signs are different, prefix $-$ to the product; and connect the partial products so obtained by their respestive signs. It is evident, that in order to render this rule applicable to the first term of the multiplicand, when that term has no sign, we must, as in the case of the operations of addition and subtraction, consider it to be preceded by $+$, as by so doing we shall obtain correct results, and include under one rule that which would otherwise require two.

A few examples will serve to render the principle upon which is deduced that portion of the rule which relates to the signs of the terms of the product, clearer and more apparent than any abstract reasonings on the nature of positive and negative terms, which, be it remembered, according to the meaning we have as yet attached to those quantities, exist only in connexion with others.

The following remarks upon the multiplication of polynomials are important to be attended to:

When all the terms of a polynomial contain the same number of dimensions, or, in other words, are of the same degree, the polynomial is said to be ***homogeneous***.

The product of two homogeneous polynomials is also homogeneous. For all the terms of the multiplicand contain by the definition of homogeneous, the same number of factors, as also do all those of the multiplier; hence, if the number of factors in any one term of the former be added to the number of factors in any one term of the latter, the sum will always be the same. But every one of the terms of the product is formed by the multiplication of a term of the multiplicand by a term of the multiplier, and the number of factors contained in it is the sum of the numbers contained in those two terms; therefore the number of factors in every term of the product is the same, being composed of the same sum, or the product is homogeneous. This circumstance affords us an easy method of detecting errors in the exponents of letters in the multiplication of homogeneous polynomials. For instance, if one of the terms of the product has 6 dimensions, and all the others 7, it is a manifest indication of a mistake having been committed in the addition of the exponents.

If the product obtained by the multiplication of any two polynomials be unsusceptible of reduction, then the number of terms contained in it is equal to the product of the number of terms in the multiplicand, multiplied by the number of those in the multiplier. This is an evident consequence of the nature of the multiplication of polynomials. If, however, the product be capable of being reduced, then, of course, when that operation has been performed, the number of its terms is less. But there are always two of its terms which never can be reduced by incorporation with any others, namely: 1°, the term resulting from the multiplication of that term of the multiplicand which contains the highest power of one of the letters, by that term of the multiplier which contains the highest power of the same letter; 2°, the term resulting from the multiplication of the two terms containing the lowest powers of the same letter in the multiplicand and multiplier. For these products must contain a power of that letter higher and lower than any other partial products, which consequently cannot be ***like terms*** in regard to them.

As the operations of algebra are effected on letters which represent no particular numbers, and which consequently may be made to stand for any, their results must be true for all numbers whatsoever; and as the nature of those operations allow us to perceive how their results are constituted, and to observe the different portions of the quantities operated on which enter into their composition, we are enabled to ascertain certain general properties of numbers which are independent of any system of numeration. The following are remarkable exemplifications of this observation, and in the form we have given them will be useful exercises.

It is required to prove

1°. That

$$(a + b)(a + b) = a^2 + 2ab + b^2;$$

or, that the square of the sum of two quantities is equal to the square of the first quantity, plus the square of the second, plus twice the product of the first and second.

2°. That

$$(a - b)(a - b) = a^2 - 2ab + b^2;$$

or, that the square of the difference of two quantities is equal to the square of the first, plus the square of the second, minus twice the product of the first and second.

3°. That

$$(a + b)(a - b) = a^2 - b^2;$$

or, that the product of the sum and difference of two quantities is equal to the difference of their squares.

These examples are of very frequent occurrence in algebra, and their results should be well remembered, as, by employing them in combination, we are enabled in certain cases to find the product of polynomials more expeditiously than by the ordinary method. Thus if $3a^2 - 5b + 2ab$ is to be multiplied by $3a^2 - 5b - 2ab$, we observe that the former of these expressions is the sum of $3a^2 - 5b$ and $2ab$, and the latter their difference; therefore their product should be equal, by (3°), to $(3a^2 - 5b)^2 - (2ab)^2$, which by (1°) is equal to $9a^4 - 30a^2b + 25b^2 - 4a^2b^2$.

Division.

In algebra, as in arithmetic, the operation of division is the reverse of that of multiplication. In the performance of multiplication, our object is to find a quantity which shall contain another quantity a certain number of times; in that of division, it is to

ascertain how many times one quantity is contained in, or can be subtracted from, another. In the one case, the two factors are given, and the product is required; in the other, the product and one of the factors is given, and the remaining factor is required.

Let us suppose that $36a^4$ is to be divided by $4a^2$, which is indicated by $\frac{36a^4}{4a^2}$. To effect this division, it is required to find a third quantity, which multiplied by $4a^2$, shall produce $36a^4$. According to the rule laid down for the multiplication of monomials, this quantity must be such, that its co-efficient multiplied by 4, may give 36, and that the exponent of the letter a in it, added to 2, the exponent of the letter a in the divisor, may be equal to 4, the exponent of that same letter in the dividend. The co-efficient of this required quantity must then be 36 divided by 4, or 9, and its exponent, $4-2$, or 2; and the quantity itself therefore $9a^2$. Similarly,

$$\frac{15a^5\,b^3\,c}{3a^3\,b}=\frac{15}{3}a^{5-3}\,b^{3-1}\,c=5a^2\,b^2\,c.$$

Hence, to effect the division of monomials, divide the co-efficient of the dividend by that of the divisor; subtract the exponent of each letter in the former from that of the same letter in the latter, and the remainder will be the exponent of that letter in the quotient; and write after the result thus obtained, all the letters which enter only into the dividend, and not into the divisor, preserving to each its particular exponent.

If we apply this rule to the division of such expressions as a^4 by a^4, in which the letter has the same exponent in the dividend and the divisor, since 4 subtracted from 4 leaves 0, the result is a^0, a new symbol to which we have as yet attached no meaning. In order to ascertain what signification we ought to attach to such an expression, we recur to its origin, and find that it is the result of an operation performed cccording to a certain rule upon a particular case, for which that rule was never intended, and to which if we apply the common principles of division, we shall obtain unity for result. For by the nature of division, a^4 divided by a^4, is 1; that is to say, the number of times which a^4 contains a^4 is one. Therefore as a^0 is an unintelligible result which has no signification, we agree that it shall represent the intelligible result obtained by the performance in a different manner of the same operation by which it is itself produced. Hence we say that

$$a^0=1.$$

Whenever, therefore, in the solution of a question we meet with a letter which has 0 for exponent, we may consider it as an indication that we have in a previous stage of the investigation divided a power of that letter by itself according to the common rule, and have neglected to remark that the quotient is 1, which we ought therefore now to substitute for the symbol which we then adopted in its place. The advantage which we derive from the employment of this symbol in this conventional signification is, that it enables us to retain in our calculations, as is frequently necessary, the trace of a letter which entered into the original expression of the question to which they relate, but which has since disappeared through the performance of a division; and this without at the same time in the slighest degree affecting the result of those calculations.

It is evident, from the above rule, that the concurrence of three conditions is necessary in order that the division of monomials may be possible:—1°, that the co-efficient of the dividend should be divisible by that of the divisor; 2°, that there should be no higher powers of any letters in the divisor than those of the same letters in the dividend; 3°, that no letter should enter into the divisor which does not also enter into the dividend. If any single one of these conditions be not fulfilled, the quotient can only be obtained under the form of a *fractional monomial*, that is, a monomial which cannot be expressed without employing the sign of division, but which can frequently be simplified.

Thus suppose that $6a^3b^2cd$ is to be divided by $4a^2bc^2$. In the first place the co-efficient 6 is not divisible exactly by the co-efficient 4; and secondly, there is a higher power of c in the divisor than in the dividend, therefore we can only obtain the quotient under the form of $\frac{6a^3b^2cd}{4a^2bc^2}$. But as both the dividend and divisor contain the common factors 2, a^2, b, and c, the quotient will not be affected by striking those factors out of each, and it will then become $\frac{3abd}{2c}$. We may satisfy ourselves of the correctness of the result we have obtained in multiplying it by the divisor, when it ought to produce the dividend. Thus $\frac{3abd}{2c}\times 4a^2bc^2$ is $3abd$, divided by $2c$, and multiplied by $2c\times 2a^2bc$, which is equivalent to $4a^2bc^2$; or as $3abd$, first divided by $2c$, and then multiplied by the same quantity, is evidently but $3abd$; the product is equal to $3abd\times 2a^2bc$, or to $6a^3b^2cd$.

Hence when the division of two monomials is impossible, indicate the performance of the operation by writing the divisor below the dividend with a line between them, in the form of a fraction; strike out the greatest common factor of the two co-efficients, subtract the exponent of the lower power of every letter which is common to both the dividend and divisor from that of the higher power of the same letter, and write that letter with the difference for its exponent in the term of the fraction to which the higher power belongs. The expression which remains after these operations have been performed, will be the most simple form in which we can obtain the quotient. According to this rule it will be be found that

$$\frac{48a^3\,b^2\,cd^3}{36a^2\,b^3\,c^2\,de}=\frac{4ad^2}{3bce}$$

$$\text{And }\frac{37ab^3c^5d}{6a^3\,bc^4\,d^2}=\frac{37b^2c}{6a^2d}$$

The division of polynomials is more complicated than that of monomials, and the principles in which it is performed may be illustrated in the following manner: Let A represent an expression which is to be divided by N, and Q, the quotient of the two. If the operation can be performed without any remainder, then $A=QN$, for by the nature of division the quotient is an expression which when multiplied by the divisor, will give the dividend. Suppose A to consist of several terms, and to be equal to $a-b+c+d$, then restating our equation, we have

(1.) $A=QN$.

(2.) $Q=a-b+c+d$.

Substituting for Q in (1.) its equivalent in (2.)

$$A = (a - b + c + d)\ N.$$

(3.) $$= aN - bN + cN + dN.$$

Suppose that we have found the first term a of the quotient; then, as N which is the divisor is known, aN is also known. Subtract this last term from the equal quantities A and $aN - bN + cN + dN$; the remainders will of course be equal, or

$$A - aN = - bN + cN + dN.$$

(4.) $$= (- b + c + d)\ N.$$

Now $A - aN$ is the remainder which is obtained by multiplying the term of the quotient a, which we have found by the divisor N, and subtracting the product from A. For the sake of convenience, call this remainder B; then

(5.) $$B = (- b + c + d)\ N.$$

or, if B be regarded as a dividend, and N still continue the divisor, $(- b + c + d)$ will be the quotient, which is all the first quotient with the exception of the part of it which we have found. Let us proceed with this new dividend as with the first one; that is, suppose that we have by some means found b, and that its sign in the quotient is —; we therefore have bN. Add this latter expression to both of the equal quantities B and $(- b + c + d)$ N, and the sums will be equal; or

$$B + bN = - bN + cN + dN + bN = cN + dN.$$

Let $B + bN$ be represented by C; then

(6.) $$C = cN + dN = (c + d)\ N$$

Again, if C be made a dividend, and N remain the divisor, the quotient is $c + d$, or all the last quotient except the part of it which we have found. We proceed as above, and find c, and therefore cN; subtracting this latter from the equal quantities C and $cN + dN$, representing $C - cN$ by D, we have

$$D = dN,$$

making D a fresh dividend, and keeping N for divisor.

Suppose that we have found d; subtracting dN from the equal quantities D and dN, we have

(7.) $$D - dN = 0,$$

or the remainder is equal to nothing. This indicates that we have now obtained all the terms of the required quotient, and that the process is completed.

If we now collect together the different terms of quotients which we have found, prefixing to each its proper sign, the result will be the quotient of A divided by N. For we have seen that the quotient of B by N is the same as all the quotient of A by N with the exception of a. Or

$$\frac{A}{N} = \frac{B}{N} + a$$

And similarly,

$$\frac{B}{N} = \frac{C}{N} + b$$

$$\frac{C}{N} = \frac{D}{N} + c$$

$$\frac{D}{N} = \frac{0}{N} + d$$

Or substituting the different values for one another,

$$\frac{A}{N} = \frac{C}{N} + a + b$$

$$= \frac{D}{N} + a + b + c$$

$$= \frac{0}{N} + a + b + c + d$$

$$= a + b + c + d.$$

We will now proceed to the application of these principles to an example in which the letters we have employed are replaced by particular expressions; as the division of $18x^2y^2 - 8x^3y + 2x^4 - y^4 - 11xy^3$, which call A by $x - y$ or N.

In our remarks on multiplication, we observed that the term which contains the highest power of any letter in a product is wholly made up of the product of the two terms containing the highest power of the same letter in the multiplier and multiplicand. Therefore as the expression A is the product of N and the required quotient, if we divide the highest power of any letter in A as $2x^4$ by x, the highest power of the same letter in N, the result $2x^3$ will be one of the terms of the quotient. In order to give a connected view of the different steps, we here insert the whole operation, accompanying each line with the corresponding step in our first process.

		(N)	(A)	(a)
		$x - y$)	$18x^2y^2 - 8x^3y + 2x^4 - 4y^4 - 11xy^3$	$(2x^3$
(a N.)	Subtract		$2x^4 \quad - 2x^3y$	
				(b)
(B.)	Second dividend		$18x^2y^2 - 6x^3y - y^4 - 11xy^3$	$(- 6x^2y$
(b N.)	Subtract		$-6x^3y + 6x^2y^2$	
				(c)
(C.)	Third dividend		$12x^2y^2 - y^4 - 11xy^3$	$(+ 12xy^2$
(c N.)	Subtract		$12x^2y^2 - 12xy^3$	
				(d)
(D.)	Fourth dividend		$- y^4 \quad + xy^3$	$(+ y^3$
(d N.)	Subtract		$+ xy^3 - y^4$	
			0	

Hence the whole quotient is $2x^3 - 6x^2y + 12xy^2 + y^3$.

After having found $2x^3$, one of the terms of the quotient, we multiply it by the division $x - y$, and subtract the product from the whole expression A. We then obtain a new dividend B, which differs only from the former in this, that it has one term less in the quotient, namely, that term which we have found. Considering B then as the product of the divisor N and the quotient, we shall by dividing the term with the highest power of x in B, by the term with the highest power of x in N, obtain one of the terms of that quotient. But the highest power of x in B, viz. $6x^3y$ has the negative sign placed before it; therefore what sign must we prefix to the quotient which results from dividing by x? We de-

termine this from the rule deduced for the signs of the terms of a product in multiplication. For as by that rule the product of two terms which have the same sign is preceded by +, and of two which different signs by —; it follows, 1°. That if a term of the dividend have the sign + and a term of the divisor +, the term of the quotient of those two must also have +; 2°. That if the term of the dividend have the sign +, and of the divisor —, the term of their quotient must be preceded by —, in order that when multiplied by the term of the divisor which has — also, their product in the dividend may be preceded by +; 3°. That if the term of the dividend has the sign —, and that of the divisor +, the sign of their quotient must be —; 4°, and lastly, that if the term of the dividend has the sign —, and that of the divisor —, their quotient must be preceded by +. These may all be reduced to the following rule:

If the term of the dividend and that of the divisor have the same sign, their quotient must be preceded by the sign +; but if they have different signs, the sign of their quotient must be —; a term which has no sign, being considered, as in multiplication, to be preceded by +.

To resume, if we divide $6x^3y$ by x, we obtain $6x^2y$, to which must be prefixed the negative sign, when it is connected with the other terms of the quotient. We then subtract the product of this term of the quotient multiplied by the divisor N, from the whole expression B, and considering the remainder as a third dividend C, which differs only from the second in having one term less in the quotient, we operate upon it as upon the two former. We thus obtain a term of its quotient $12xy^2$; and regarding the remainder which results from the subtraction of its product by N from the whole of C, as a fourth dividend D, we find a term of its quotient, y^3; subtracting the product of this by N from D, the remainder which we obtain is nothing; thus indicating that the operation is finished.

In examining the preceeding operation, we perceive that in operating upon each dividend, we are obliged to find out the term in it which contains the highest power of x in order to divide it by the term of the divisor containing the highest power of the same letter. It is evident then that we should avoid the necessity of this search, if we previously wrote each of those expressions with the term containing the highest power of x first, the highest power but one, second, the next, third, and so on, arranging it as it is called in descending powers of x. By this means we are enabled always to know where to look for the highest power of the letter, in powers of which the expression is arranged both in the dividend and divisor. In the example which we have given, the letter x enters but into one term in the divisor, but in more complicated expressions where it occurs frequently, the full advantage of this arrangement is felt as well as in the dividend. Hence, to divide one polynomial by another, arrange both the divisor and dividend in powers of the same letter; divide the first term in the dividend by the first term in the divisor, and the result will be the first term of the required quotient; multiply the whole divisor by this term, and subtract the product from the whole dividend. Then divide the first term of the remainder by the first term of the divisor, and the result will be the second term of the quotient; multiply this term by the divisor, and subtract the product from the first remainder. Repeat this operation until the remainder obtained is 0, in which case the division is complete. The sign of each term is determined according to the rule we have already given on that point.

When the first term of a dividend arranged in powers of any letter is not exactly divisible by the first term of a divisor arranged in powers of the same letter, it is an indication that the complete division of the whole expression is impossible; that is to say, there is no polynomial which multiplied by the divisor will give the dividend; or the division is impossible when the first term of any one of the partial dividends is not divisible by the first term of the divisor.

It is evident that there is no objection to commencing by dividing the term of the dividend which contains the lowest powers of any letter by that containing the lowest power of the same letter in the divisor; for the term containing the *lowest* power of any letter in a product is also made up of nothing but the product of the two terms containing the lowest powers of the same letter in the multiplicand and multiplier. In so doing we might still arrange the divisor and dividend in descending powers of one of the letters, and commence with the last instead of the first, or adopt the method of writing them in the contrary order with the lowest powers first, the lowest but one next, and so on, arranging them as it is called in ascending powers of that letter.

The various partial operations of which every division is composed according the above rule, as we have shown, are perfectly distinct operations. We find one term of the quotient, and by the subtraction of the product of that term by the divisor from the dividend, we obtain a new dividend, the quotient of which by the same divisor is, as we have proved, all the quotient we are in search of, except the one term which we have found. We do not however find this second quotient, and add it to the term already obtained of the first, by which means we should get the whole quotient required; but we find only one term of it, and subtracting its product by the divisor from the second dividend, we operate upon the remainder as a fresh dividend, and continue so on until we obtain a dividend equal to nothing. So perfectly independent of each other are the partial operations we perform on these dividends, that we might arrange any one of them in powers of a different letter, if we arranged the divisor in a similar manner; the term we should obtain by dividing the first term in it, by the first in the divisor, would be one of the terms of the quotient.

It may happen that either the dividend or the divisor, or both of them, may have several terms, each of which contains the same power of the letter in powers of which we wish to arrange them. Thus, suppose that

$24a^2b - 24abc + 12ab^2 - 6a^2c - 8b^2c + 8bc^2 + 9a^3$

is to be divided by $3a^2 + 6ab - 4bc$;

if we proceed to arrange the dividend in powers of a, we find that $24a^2b$ and $6a^2c$ both contain the same power of that letter; we may evidently write them thus, $(24b - 6c)\, a^2$, but it is much more convenient to dispose of them in the following form:

$$\begin{array}{r|l} 24b & a^2 \\ -6c & \end{array}$$

that is, writing a^2 only once to the right of a vertical line, to the left of which are placed in the same column the remaining portions of all the several terms which contained that power of a; this assemblage of quantities to the left of the line is by an extension of

the definition considered as the co-efficient of a^2. Similarly, $24abc$ and $12ab^2$ is written

$$\begin{array}{r|l} 12b^2 & a \\ -24bc & \end{array}$$

and the whole arrangement with the operation performed,

$$\begin{array}{r|l|l} 9a^3+24b & a^2+12b^2 & a-8b^2c+8bc^2 \\ -6c & -24bc & \\ \hline 6b & a^2+12b^2 & a-8b^2c+8bc^2 \\ -6c & -12bc & \\ \hline \end{array} \left\} \begin{array}{l} 3a^2+6ab-4bc \\ \hline 3a+2b-2c \end{array} \right.$$

$$-6ca^2-12bc\,a+8bc^2$$

In this operation we have adopted the contracted method of subtracting immediately from the dividend the partial product of each term of the divisor by that of the quotient, as soon as that product is formed, and of writing down only the remainder. We have also disposed the divisor in a different, and much more convenient manner, than before; for as each term of the quotient is found, it is placed beneath the divisor, so as greatly to facilitate the multiplication of the two. In order to investigate the general principle of a case of the nature of the preceding, which is the most complicated in division, let the dividend be denoted by $Aa^4+Ba^3+Ca^2+Da+E$, and the divisor by $A'a^2+B'a+C'$, in which A, B, C, D, E, A′ B′ and C′ represent the respective co-efficients (using this word in the extended definition we have just given) of the various letters to which they are attached. Then since the highest exponent of a in the dividend is 4, and in the divisor 2, it will be 2 in the quotient, which must be of the form of $A''a^2+B''a+C''$. The portion Aa^4, containing the highest power of a in the dividend, is the unreduced result of the multiplication of $A'a^2$ and $A''a^2$, which are the highest powers of the same letter in the divisor and quotient; therefore, to find the portion $A''a^2$ of the quotient, it is only necessary to divide Aa^4 by $A'a^2$, which since a^4, divided by a a^2, is a^2, is the same as dividing A by A′, and then multiplying the result by a^2. The polynomials A and A′, must then themselves be arranged in powers of some letters which they contain; and the former being divided by the latter, we shall obtain A″, and consequently $A''a^2$, or the assemblage of all those terms of the quotient which contain the highest power of a. This separate division having been performed, we return to the principal operation, and multiplying the divisor by $A''a^2$, we subtract the product from the dividend A, and proceed with the remainder as with the original dividend, and so on. The following is an example of this nature, to which we have attached the partial divisions induced by the principal operation:—

$$\begin{array}{r|l|l|l} -12b^2 & a^3+23b^3 & a^2+10b^4 & a \\ -29bc & -31b^2c & -6b^2c^2 & \\ +15c^2 & -9bc^2 & & \\ & +15c^3 & & \\ \hline & +15b^3 & a^2+10b^4 & a \\ & -25b^2c & -6b^2c^2 & \\ & -9bc^2 & & \\ & +15c^3 & & \\ \hline \end{array} \left\} \begin{array}{r|l|l} 3b & a+2b^2 & \\ -5c & & \\ \hline 4b & a^2+5b^2 & a \\ -3c & -3c^2 & \end{array} \right.$$

$$0$$

First Partial Division.

$$\text{(A)}\ \begin{array}{r} 12b^2+29bc-15c^2 \\ \hline -9bc+15c^2 \\ \hline 0 \end{array} \left\} \begin{array}{l} 3b-5c\ \text{(A′)} \\ \hline 4b-3c\ \text{(A″)} \end{array} \right.$$

Second Partial Division.

$$\text{(B)}\ \begin{array}{r} 15b^3-25b^2c-9bc^2+15c^3 \\ \hline -9bc^2-15c^3 \\ \hline 0 \end{array} \left\} \begin{array}{l} 3b-5c\ \text{(A′)} \\ \hline 5b^2-3c^2\ \text{(B″)} \end{array} \right.$$

Under the head of *Division* we shall give a few examples of that operation which are of remarkable application, and of very frequent use in the solution of questions. For a continuation of the subject of Algebra, see *Measure, greatest common; Equations, of the First Degree; Negative Sign; Equations, of the Second Degree; Indeterminate Analysis; Permutations and Combinations; Binomial Theorem; Powers, Formation of; Roots, Extraction of; Surds; Negative Exponents; Fractional Exponents; Series; Proportions; Progressions; Logarithms; Interest and Annuities; Logarithmic and Exponential Series; Equations, Theory of,* &c. in the order we have enumerated them.

Aliment; a term which includes every thing serving as nutriment for organized beings. In animals and vegetables we can observe the phenomena of decomposition and reproduction, and analyze the substances that administer to their growth and repair distinctly. Generally, however, the word aliment is used for what serves as nutriment to animal life. It is, in this respect, a subject of great interest for the zoologist. In the present article we shall confine ourselves to the aliment of mankind. Man, it is well known, derives nourishment both from animal and vegetable substances. He eats fruits, both ripe and unripe, roots, leaves, flowers, and even the pith and the bark of different plants, many different parts of animals, and the whole of some. Climate, custom, religion, the different degrees of want and of civilization, give rise to an innumerable diversity of food and drink, from the repast of the cannibal savage of New Zealand to that of the Parisian epicure at the table of Verrey; from the diet of the carnivorous native of the north to that of the Brahmin, whose appetite is satisfied with vegetables; from the oak-bark bread of the Norwegian peasant to the luxuriously-served table of a Hungarian magnate at Vienna. Some nations abhor what others relish, and great want often renders acceptable what, under other circumstances, would have excited the greatest disgust. The flesh of dogs is commonly eaten in China, and in Africa that of snakes, particularly of the rattlesnake and boa-constrictor. Locusts are eaten both in Asia and Africa, and the Negroes on the coast of Guinea relish lizards, mice, rats, snakes, caterpillars, and other reptiles and worms. The Otomacs, a tribe of American Indians, are said by Humboldt to collect a kind of clay to eat in the rainy season. It is an interesting subject, by no means sufficiently investigated as yet, how far the different aliment of various countries is connected with the climate, &c., and what influence it exerts on the different races, as well as the consequences of introducing new species of aliments. Some excellent remarks on the national dishes of different nations were published by Baron Rumor, a German, in 1822, in a work which he called *Kochkunst* (Art of Cookery). All kinds of aliment must contain nutritious substance, which being

extracted by the act of digestion, enters the blood, and effects by assimilation the repair of the body. (See NUTRITION.) Alimentary matter, therefore, must be similar to animal substance, or transmutable into such. In this respect, alimentary substances differ from medicines, because the latter retain their peculiar qualities in spite of the organs of digestion, and will not assimilate with the animal substance, but act as foreign substances, serving to excite the activity of particular organs or systems of the body. All alimentary substances must therefore be composed in a greater or less degree, of soluble parts, which easily lose their peculiar qualities in the process of digestion, and correspond to the elements of the body. These substances, in their simple state, are mucilage, gelatin, gluten, albumen, farina, fibrin, and saccharine matter. Of these, vegetables contain chiefly mucilage, saccharine matter, and farina, which latter substance, particularly in connexion with the vegetable gluten, by which both become apt for fermentation, and thus for dissolution and digestion, is the basis of very nutritious food. The nutritive part of fruits consists of their saccharine matter and a little mucilage. In animal food, gelatin is particularly abundant. The nutritiousness of the different species of food and drink depends, therefore, upon the proportion which they contain of those substances, and the mode in which they are connected, favouring or obstructing their dissolution. Organs of digestion in a healthy state dissolve alimentary substances more easily, and take up the nutritious portions more abundantly, than those of which the strength has been impaired so that they cannot resist the tendency of each substance to its peculiar chemical decomposition. The wholesome or unwholesome character of any aliment depends, therefore, in a great measure, on the state of the digestive organs, in any given case. Sometimes a particular kind of food is called wholesome, because it produced a beneficial effect of a particular character on the system of an individual. In this case, however, it is to be considered as a medicine, and can be called wholesome only for those whose systems are in the same condition. Very often a simple aliment is made indigestible by artificial cookery. Aliments abounding in fat are unwholesome, because fat resists the operation of the gastric juice. The addition of too much spice makes many an innocent aliment injurious, because spices resist the action of the digestive organs, and produce an irritation of particular parts of the system. They were introduced as artificial stimulants of appetite. In any given case, the digestive power of the individual is to be considered, in order to determine whether a particular aliment is wholesome or not. In general, therefore, we can only say, that that aliment is healthy, which is easily soluble, and is suited to the power of digestion of the individual; and, in order to render the aliment perfect, the nutritious parts must be mixed up with a certain quantity of innocent substance affording no nourishment to fill the stomach, because there is no doubt that many people injure their health by taking too much nutritious food. In this case, the nutritious parts which cannot be dissolved act precisely like food which is in itself indigestible. (See DIGESTION.) In Prussia and Austria, where, as in many despotic governments, the medical police is very good (this being a thing much more easily regulated in an absolute government than in a free one), the public officers pay much attention to aliment, and are careful that provisions exposed to sale shall be of a good quality, particularly that no decayed or adulterated things are sold to the poor. Such regulations exist, to a certain extent, in England, France, the United States of America, and in fact in every civilized country. The kind of aliment used, influences the health and even the character of man. He is fitted to derive nourishment both from animal and vegetable aliment, but can live exclusively on neither. Experience proves that animal food most readily augments the solid parts of the blood, the fibrin, and therefore the strength of the muscular system, but disposes the body at the same time to inflammatory, putrid, and scorbutic diseases, and the character to violence and coarseness. On the contrary, vegetable food renders the blood lighter and more liquid, but forms weak fibres, disposes the system to the diseases which spring from feebleness, and tends to produce a gentle character. Something of the same difference of moral effect results from the use of strong or light wines. But the reader must not infer that meat is indispensable for the support of the bodily strength. The peasants of some parts of Switzerland, who hardly ever taste any thing but bread, cheese, and butter, are vigorous people. The nations of the north incline generally more to animal aliment; those of the south, and the Orientals, more to vegetable. The latter are generally simpler in their diet than the former, when their taste has not been corrupted by luxurious indulgence. Some tribes in the East, and the caste of Brahmins in India, live entirely on vegetable food. The inhabitants of the most northern regions live almost entirely upon animal food, scarcely ever partaking of any vegetable substance, at least during the greater part of the year. Some nations feed chiefly on terrestrial animals, others on aquatic ones.

ALIMENTARY CANAL, in *Anatomy*, the whole tract of intestines, including the stomach.

ALIMENTARY DUCT, the same as the thoracic duct.

ALKAHEST, or ALCHAHEST, in *Chemistry*, a name first used by Paracelsus, by whom it was probably coined to signify an universal menstrum. It is explained by Van Helmont to signify a salt of the highest sort, that had attained to the highest state of purity and subtilty. It was supposed to possess the virtue of pervading every substance; and while it acted on every thing else, it remained itself immutable.

ALKALI, in *Chemistry;* from the Arabian *kali*, the name of a plant from the ashes of which one species of alkali can be extracted. The substances that are met with under the denomination of alkaline, are possessed of certain peculiar properties; they are mainly characterized, however, by a power of combining with acids in such a manner as to impair the activity of the latter, so that alkalies, as chemical agents, are distinguished by properties the reverse of acids; acids and alkalies are, therefore, generally considered as antagonist substances. Besides the power of neutralizing acids, and thereby forming certain saline substances, the alkalies are further distinguished by the following properties:—1, they have an acrid taste and corrosive power when applied to some substances, thus proving caustic to the skin and tongue; 2, they change vegetable blue to green, red to purple, and yellow to a reddish brown (if the purple be reddened by an acid, an alkali will restore the original colour); 3, they are almost indefinitely soluble in water; that is, they combine with it in every proportion; 4, they unite with oils and fats, and form by this union the

well-known compound called *soap*. There is another class of substances which have a strong analogy with alkalies, especially in the particular of opposition to acids, viz. the earths. Some of these, indeed, have been classed by Fourcroy among the alkalies, but they have been kept separate by others, on the ground that the analogy between them is far from amounting to an identity of properties. The true alkalies have been arranged by a modern chemist in three classes:—1°, those which consist of a metallic basis, combined with oxygen; these are 3 in number—potash, soda, and lithia; 2°, that which contains no oxygen, viz. ammonia; 3°, those containing oxygen, hydrogen, and carbon; in this class are placed aconita, atropia, brucia, circuta, datura, delphia, hyoscyamia, morphia, strychina. It is supposed that the vegetable alkalies may be found to be as numerous as the vegetable acids. The original distribution of alkaline substances was into volatile and fixed, the volatile alkali being known under the name of *ammonia;* while, of the two fixed kinds, one was called *potash* or *vegetable*, because procured from the ashes of vegetables generally; the other, *soda* or *mineral*, on account of its having been principally obtained from the incineration of marine plants.

Allegro, in *music;* a word denoting one of the six distinctions of time. It expresses a sprightly motion, the quickest of all, and originally means gay. The usual distinctions succeed each other in the following order—*grave, adagio, largo, vivace, allegro, presto*. Allegro time may be heightened, as *allegro assai* and *allegrissimo*, very lively; or lessened, as *allegretto* or *poco allegro*, a little lively. *Più allegro* is a direction to play or sing a little quicker.

Alloy; a composition, the result of a mutual combination of two or more metals. To alloy generally means to mix a metal of less with one of more value. Various processes are adopted in the formation of alloys, depending upon the nature of the metals. Many are prepared by simply fusing the two metals in a covered crucible. It has been a question whether alloys are to be considered as compounds, or as mere mixtures. Mr. Dalton considers alloys to be chemical compounds, one striking instance of which is in the alloy of tin and copper, called *speculum metal;* the smallest deviations from the true proportions will spoil the alloy as a reflector. In some cases, the metals are found to unite in definite proportions only; and it is probable that all the alloys contain a definite compound of the two metals. The principal characters of the alloys are the following:—1. We observe a change in the ductility, malleability, hardness, and colour. Malleability and ductility are usually impaired, and often in a remarkable degree; thus gold and lead, and gold and tin, form a brittle alloy. The alloy of copper and gold is harder than either of its component parts; and a minute quantity of arsenic added to copper renders it white. 2. The specific gravity of an alloy is rarely the mean of its component parts; in some cases an increase, in others a dimunition of density having taken place. 3. The fusibility of an alloy is generally greater than that of its components. Thus platinum, which is infusible in our common furnaces, forms, when combined with arsenic, a very fusible alloy; and an alloy of certain proportions of lead, tin, and bismuth is fusible at 212°; a temperature several degrees below the melting point of its most fusible constituent. 4. Alloys are generally more oxydizable than their constituents taken singly; a property which is, perhaps, partly referable to the formation of an electrical combination. From early times, the baser metals have been used to alloy gold and silver coins, to prevent loss by wear. In England, the legal proportion of base metal for gold coin is 1 part in 12, and for silver coin 3 parts in 40. In France the legal proportions of the different coins are as follow: silver coin, 9 parts silver, 1 copper; copper money, 4 parts copper, 1 silver; gold coin, 9 parts gold, 1 copper. For silver plate, the French proportions are 9½ parts silver, ½ copper; for trinkets, 8 parts silver, 2 copper. For gold plate they have three different standards; 92 parts gold, 8 copper; also, 84 gold, 16 copper, and 75 gold, 25 copper. Gold and silver are alloyed partly that they may wear better, partly to diminish the price of articles made of them.

Almacantor. A name for the parallels of altitude on the celestial globe, whose zenith is the pole or vertical point.

Almond, a Portuguese measure of oil, equal to four gallons and a half.

Almond, in *Anatomy*, a name for the glandular substances on each side of the uvula at the root of the tongue, otherwise called *tonsillæ*.

Altitude denotes the perpendicular height of the vertex of any plane or solid body, above the line or plane of its base; thus the altitude of a triangle is measured by a perpendicular let fall from any one of its angles upon the base, or upon the base produced; therefore the same triangle may have different altitudes, accordingly as we assume one side or another for its base. Again, the altitude of a cone or pyramid, whether right or oblique, is measured by a perpendicular let fall from the vertex to the plane of its base. Similar remarks apply to other solids. In astronomy, altitudes are measured or estimated by the angles subtended between the object and the plane of the horizon; and this altitude may be either *true* or *apparent*. The *apparent* altitude is that which is obtained immediately from observation; and the *true* altitude that which results from correcting the apparent altitude, by making allowance for parallax, refraction, &c. The altitude of a terrestrial object is the height of its vertex above some horizontal plane assumed as a base. The altitude of mountains is measured generally from the level of the ocean; that is, the altitude of a mountain is the difference between the mean terrestrial radius, and the distance of the vertex of the mountain from the centre of the earth. If the altitude of a mountain is given without any explanation, the altitude above the ocean is always understood. This altitude can be measured trigonometrically, by barometrical observations, or by actually measuring the level between the base and vertex of an object; and, if very great accuracy is not required, by optical reflection, by the length of shadows, moveable staves, the geometrical square, &c.; and, generally, by any method in which the calculation depends upon the similarity of plane rectilinear triangles.

Alto, or Alto Tenore. *Alto* is the term applied to that part of the great vocal scale which lies between the *mezzo soprano* and the tenor, and which is assigned to the highest natural adult male voice. In scores it always signifies the counter-tenor part.

Alum, *artificial*. Common alum is a triple salt, consisting of sulphuric acid, alumine, potash, and water, or of sulphate of alumine, and sulphate of pot-

ash, united together with a certain quantity of water of crystallization. It crystallizes in regular octahedrons, which are generally truncated on their edges and solid angles. Alum may also be formed by substituting either soda, ammonia, or magnesia for the potash, without at all altering its crystalline form or its taste. It dissolves in 5 parts of water, at 60°, and the solution reddens vegetable blues, indicating the excess of acid which this salt contains. Exposed to heat, it undergoes a watery fusion, and becomes light and spongy, in which condition it possesses slightly corrosive properties, and is used as a caustic, under the name of *alumen exsiccatum*. The simplest process by which alum is prepared is, perhaps, that adopted at the Solfatara near Naples, which is covered with a white clayey soil, through which sulphureous vapours are constantly emitted. This soil is always hot, and nothing more is requisite than to immerse into it cisterns, and subject the earthy matter to lixiviation; after which, the saline solution is evaporated by means of the subterranean heat also, and placed in a situation to cool, when the alum is deposited in crystals. As nothing is added during the process, it is obvious that the alum must exist ready formed in the soil. From the presence of a small portion of iron, the Solfatara alum is not so valuable, for many purposes, as that produced elsewhere; and accordingly its use is mostly confined to the Neapolitan states. The manufacture of alum directly from its component parts has of late years furnished a large proportion of this substance found in commerce. The process is conducted in the following manner: sulphur and nitrate of potash (nitre) are mixed together, in the proportions for forming sulphuric acid, and brought into combustion in large leaden chambers, or rooms lined with a thick coating of plaster. The sulphur is thus acidified and converted into vapour, and the floor of the apartment being covered with clay of the purest kind, previously calcined, the acid gradually combines with it, and forms sulphate of alumine, which after a few days is dissolved out and considerably reduced by evaporation, when a solution of sulphate of potash (being the residue of the combustion of the nitre and sulphur) is poured in, and the perfect crystals of alum are deposited. The importance of alum in the arts is very great, and its annual consumption is immense. It is employed to increase the hardness of tallow, to remove greasiness from printers' cushions, and blocks in calico manufactories, and to render turbid waters limpid. In dyeing, it is used to cleanse and open the pores on the surface of the substance to be dyed, and by the attraction of the colouring matter for the alumine it contains, to render it fit for receiving the colouring particles. Wood and paper are dipped into a solution of it to render them less combustible. Paper impregnated with alum is useful in whitening silver, and in silvering brass without heat. It is also largely used in the composition of crayons, in tannery, and in medicine.

The discovery of alum is entirely unknown; all attempts to trace the origin of its manufacture have been quite unsuccessful. In the middle ages, alum-works existed at Rocca in Syria, since called Edessa, whence probably the commercial name of rock-alum, at Foya Nova, near Smyrna, and in the vicinity of Constantinople. From these places the Genoese, and other commercial states of Italy, procured the alum with which they supplied the western and northern parts of Europe. About the middle of the fifteenth century this manufacture was introduced into Italy, and the establishments of La Tolfa, Viterbo, and Volaterra, soon acquired an importance which induced Pope Pius II. to prohibit the use of oriental alum. Early in the sixteenth century the art of preparing this salt extended to Spain and Germany. The alum-works of Whitby, in England, were established in the reign of Charles I., by Sir Thomas Chaloner; and in the seventeenth century the manufacture of alum began also to be undertaken in Sweden.

Alum was well known by the older chemists to contain an earth in combination with sulphuric acid; but from its being precipitable in a white pulpy mass by a carbonated alkali, and being again soluble with effervescence in an acid, the common opinion for a long time was that this earth was calcareous, and therefore that there was a considerable analogy between alum and selenite. Geoffroy, Barron, Hellot, and Pott, in their interesting experiments on this salt, showed that its earthy base was contained in clay; and Marggraf, in his two memoirs on this subject, made a still nearer approach to the knowledge of its constituent parts. He showed that the precipitated earth of alum, when well washed, is resoluble in sulphuric acid, even after it has been calcined, but that this solution yields on evaporation only a saline magma, instead of crystals of alum: the same effect takes place if a native clay is used, instead of the earth of alum. This able chemist also proved that the addition of a little potash to the sulphate of alumine, communicated to it the property of depositing octahedral crystals of genuine alum: he seems however to have considered the alkali only to be of use in combining with and neutralizing a certain oily or greasy matter, which by adhering to the crystalline plates of the magma, prevented them from coalescing into hard and perfect crystals. The essay of Bergman, on the preparation of alum (published first in 1767), added considerably to our knowledge of the ingredients and chemical properties of this salt: it is here shown that a small excess of acid is necessary to the constitution of alum; since, when this is taken away, its taste, solubility, and crystallizability are destroyed. The author also mentions, in the same treatise, that those lixivia, which on account of their great excess of acid cannot by mere evaporation be made to deposit alum, may be brought to a crystallizable state by the addition of potash or ammonia, but not by means of soda or lime. He further observes, that vitriolated potash and alum combine into a triple salt; yet is by no means of opinion that all alum necessarily contains either potash or ammonia; on the contrary, he recommends the acid uncrystallizable lixivia to be treated with clay, in order to neutralize their great excess of acid, and dispose them to deposit a larger quantity of crystals than could be procured from the addition of potash. This proposed improvement of the manufacture was introduced without success into some of the German establishments, and many of the chemists of that nation began to consider alum as a proper triple salt, in which the presence of potash or ammonia was absolutely necessary: Professor Hildebrand, and Klaproth, in particular, were decidedly of this opinion. It is to the accurate and indefatigable Vanquelin, however, that chemistry is indebted for the latest and most satisfactory experiments on this subject, which have

scarcely left any thing further to be known relative to the composition of this salt.

He first dissolved in pure sulphuric acid some alumine equally pure, and then evaporated the solution repeatedly to dryness, in order to drive off the excess of acid: the dry pulverulent residue being then redissolved in water, was brought by evaporation to various states of specific gravity for the purpose of crystallization; but notwithstanding every precaution, a flaky crystalline residue was all that could be procured. The solution which had thus constantly refused of itself to yield crystallized alum, began to deposit some immediately on the addition of a few drops of carbonated potash; and by accurately proportioning the alkali, the whole of the liquor to the very last drop was made to furnish by evaporation octahedral crystals of alum.

Another portion of the same pure aluminous sulphate was mixed with the same quantity of carbonated soda as had been employed of potash in the preceding experiment, but no crystals were deposited, even by evaporation. Nor were lime or barytes more efficacious. Hence it may be inferred that alum is by no means a pure sulphate of alumine, and that the use of potash in promoting its crystallization is not to saturate a supposed excess of acid. This was further demonstrated by substituting sulphate of potash and sulphate of ammonia for these alkalies in their pure or carbonated states; in which case, being already saturated with sulphuric acid, they could not possibly contribute to deprive the aluminous sulphate of a supposed excess of the same acid; yet in this case, as in the former, the uncrystallizable sulphate of alumine was made to deposit crystals of genuine alum. The same effect took place even when acidulous sulphate of potash was substituted for common sulphate of potash.

Alum, *native*, is found in most countries in the state of an efflorescence or mould upon the surface of certain slate clays and lavas, and in the United States in mica-slate rocks; also, in delicate hair-shaped fibres, occupying clefts in a bituminous shale, principally found in Italy. It may always be easily recognized by its sweetish, astringent taste, in which it resembles the artificial alum. It exists only in very limited quantities, and contains too many impurities to be of any practical use.

Alumina. This earth has neither smell nor taste while dry; it is soft to the touch, and adheres strongly to the tongue; by exposure to an intense heat it is imperfectly fused, and becomes so hard as to strike fire with steel, and to be capable of cutting glass. Its specific gravity is 2.00. It is scarcely soluble in water; but when dry, it is capable of absorbing 2½ times its weight of water, and easily mixes with a greater quantity to form a paste: it is soluble in all acids, and in solutions of caustic, potash, and soda. It is often called argil or pure clay. Alumina derives its name from alum, from which salt it is obtained in the greatest purity. Common alum is chiefly a sulphate of alumina; common clay is alumina mixed with silex, and several other bodies.

Ignition renders alumina incapable of forming a paste with water; but it recovers this property by solution and precipitation.

To obtain alumina, dissolve alum in hot water, and add ammonia or potash to the solution, as long as any precipitate is formed. Decant off the fluid, and wash the precipitate in a large quantity of water. This precipitate is alumina, combined with only a small portion of sulphuric acid, whereas, in the state of alum, it was supersaturated with the acid. If this precipitate be dissolved in muriatic acid; the solution evaporated till it deposits crystals in cooling; these crystals separated each time after repeated concentrations of the solution; and, lastly, a precipitate formed by ammonia, alumina nearly pure will be obtained; the crystals separated consisting of the alum.

Alumina cannot be artificially crystallized; but it is found native in beautiful transparent crystals, of great hardness, and of the specific gravity of 4. In this state it forms the precious stone called sapphire.

Though alumina alone is exceedingly refractory in the fire, yet it easily fuses and enters into combination with lime, for which it has a strong affinity. Alumina has also a strong affinity for metallic oxides, particularly those which contain most oxygen. The various colours of clay are mostly owing to the oxide of iron combined with them.

Alumina is of great importance to mankind; it enters largely into the composition of the best arable soils; as it swells and will not permit water to pass through it, it is inestimable as a lining for canals and reservoirs; for this purpose it is used in the state of clay; combining readily with greasy substances, it is also of the first importance in scouring cloth, to which use it is often applied in the form of pipe-clay; but, in manufactures, fuller's earth is chiefly used, which is alumina mixed with very fine silex. Clay is also extensively required for making bricks and tiles. Alumina is the base of all earthenware and porcelain, and its utility for these purposes renders it of great consequence. In one province of China, five hundred furnaces and nearly a million of men, are said to be employed in the manufacture of porcelain.

The basis of alumina is the metal aluminum, which may be obtained in the form of a grey powder, by causing potassium to act on chloride of aluminum. It burns splendidly in oxygen; and an oxide is procured, which is alumina consisting, according to Thomson, of 100 parts of aluminum, and 8 of oxygen.

Amalgam. The alloy of mercury with any metal, if the mercury predominates so far as to render it soft, and of the consistence of butter, is called an amalgam. These amalgams are much employed in silvering and gilding, as the mercury is easily driven off by heat, and the fixed metal is left behind. The metal with which the backs of looking-glasses are coated, is an amalgam of tin and mercury.

Amalgam, *Electrical*. Various compounds are made under this name. They are differently prepared, but the best are made of tin and mercury, or zinc and mercury. Cavallo directs the amalgam of tin to be made by mixing two parts of mercury with one of tin-foil, adding a little powdered chalk, and mixing the whole until it becomes a mass like paste. For the amalgam of zinc, heat four or five parts of mercury higher than the boiling point of water, and have in readiness one part of melted zinc. Pour the heated mercury into a wooden box, and immediately after pour the melted zinc upon it. Close the box, and shake it for about half a minute. After the amalgam thus made is cold, mix it by trituration, with a small quantity of grease, such as tallow, mutton suet, &c., a very small quantity of finely powdered whitening,

and about a fourth part of the above amalgam of tin. This amalgam of zinc is the best.

Ammonia. The volatile alkali for which this is but another name, has already been noticed in our account of the alkalies; but we purpose on the present occasion going fully into its chemical properties, as well as its application to the useful arts.

Ammonia is obtained for actual use only from vegetable and animal substances, more especially the latter; in a few instances that we shall presently mention, it is also formed by the union of its constituent parts in the course of certain chemical experiments. The distillation of animal or vegetable matter has long been known to furnish an ammoniacal product, partly liquid, partly concrete, and capable of being purified by subsequent rectification, which has been termed salt or spirit of hartshorn, spirit of wine, &c., according to the substance employed.

In all these cases the volatile alkali is disengaged in a carbonated state, and is accordingly strongly effervescent with acids. This subject we shall refer to the articles *Carbonate of Ammonia*, and *Animal Matter*, and we shall here only describe the properties of ammonia in its pure and caustic state, and the facts which prove its chemical composition. All these facts are comparatively modern. Dr. Black first pointed out the difference between the caustic and mild alkalies, and the respective states of ammonia among the rest; and Dr. Priestley appears to have been the first who obtained this alkali in its purest form, that of a gas, and has termed it alkaline air.

Ammonia is thus prepared: Take any quantity of well-burnt lime, slack it with a little water, so as to reduce it to a powder, then mix it expeditiously with half its weight of dry muriate of ammonia in fine powder. On the instant of mixture, very pungent suffocating fumes of volatile alkali will be disengaged (which should be avoided, as they would excoriate the nostrils), and the mixture should be put into a retort of glass or earth, or into an iron or earthen tube, closed at one end, and closely fitted with a stopper, to which a bent glass tube is cemented. On the application of a very moderate heat, by a lamp or a pan of charcoal, the ammoniacal gas will be given off in great abundance for a considerable time, and to be examined chemically must be received in a jar filled with mercury and standing over the same fluid. In this operation the ammonia is disengaged from the muriatic acid, which combines with a portion of the lime, so that after all the alkali has been expelled, muriate of lime, with a great excess of lime, remains in the retort. This when duly heated is phosphoric. A much smaller quantity of lime is sufficient for the expulsion of the ammonia. Mr. Cornette found by direct experiment, that when equal parts of lime and muriate of ammonia were used, all the alkali was given out by heat, and in the residue which contained no undecomposed muriate of ammonia, nearly a fifth of the lime remained uncombined. On using three times the quantity of lime, no more ammonia was obtained than with only equal parts.

Many other substances will decompose muriate of ammonia and expel the alkali. The oxides of lead, minium, and litharge, assisted by heat, may be used with advantage, and the residue is muriate of lead. Water absorbs ammoniacal gas with great ease, but yields it again when heated to about 130°, and hence the liquid ammonia affords a very ready method of furnishing the gaseous alkali, nothing more being necessary than to put the liquor into a proof bottle with a curved tube, or any similar vessel, to heat it with the flame of a taper, and to collect the gas over mercury. No greater heat than necessary should be used, otherwise the steam of the water driven over along with the gas, will absorb it again rapidly on cooling.

Ammonia remains a permanent gas unaltered at any known temperature under a red heat. In this state it is intensely pungent and caustic, excoriating the nostrils when snuffed up unmixed, producing a most acrid sensation to the tongue and a dangerous constriction of the larynx. In a dilute form it is gratefully pungent and refreshing. Small animals immersed in it are instantly killed. The specific gravity of ammonia is not easily ascertained with perfect accuracy, owing to the extreme ease with which this gas combines with moisture in large proportions.

According to Mr. Kirwan's experiments, 100 cubic inches of this gas at 61° temperature and 30 inches barometrical pressure, weigh 18.16 grains. The same quantity of common air he estimates at 31 grains, and hence the alkaline air is lighter than the common air in the proportion of about 6.10. Therefore, as the specific gravity of common air (being 816 times lighter than water) is .0012255, the specific gravity of ammonia is .0007353. Other experiments nearly agree with this estimation of alkaline air.

This gas has been commonly represented as remarkably dilutable by heat, much more so than common air in similar circumstances. This has been actually observed by Priestley, Guyton, and other chemists, but it appears to apply only to this gas in its common state. The experiments of M. du Vernois prove that much of this expansion by heat is owing to the quantity of water that is vapourized along with the alkali, which quantity being variable, throws an equal irregularity on the results. He attempts however to give the following comparison as an approximation to the truth. 100 cubic inches of common air at 32°, and the same quantity of ammoniacal gas (procured from dry muriate of ammonia and lime) also at 32°, are respectively expanded at the different temperatures in the following ratio:

	Common air.	Common gas.
at 77°	107.89	127.91
122	125.70	184.87
167	165.74	358.78
212	193.68	680.09

But independently of the error arising from the admixture of aqueous vapour, it has been supposed that even in the heat of boiling water, a small portion of the alkaline gas is decomposed by the mercury over which it is confined, and which is generally slightly oxidated at the surface, and we shall presently see how readily the metallic oxides act upon the alkali.

Mr. Gay-Lussac, in his valuable experiments on the dilatation of gases, gives another cause of error in the experiments on alkaline air. In receiving the gas directly from the mixture of lime and muriate of ammonia, he did indeed find it much more dilatable by heat than common air; but on cooling the gas, he observed it to deposit a liquid with crystalline points of a salt, which he took to be either muriate or carbonate of ammonia, all of which again disappeared on raising the temperature. To exclude this impurity, he repeated the experiment with ammonia that had

previously remained in contact with potash, and now no longer gave this deposition on cooling. This gas was now found to expand exactly in the same ratio as common air by equal increments of heat from the freezing point to 203°.

A high heat decomposes the alkali, as will presently be seen.

Ammoniacal gas extinguishes flame. When a lighted taper is plunged into a jar full of this air, it immediately goes out, but just before extinction the flame is enlarged by a kind of halo of a pale yellow colour. The electric spark taken in it is red.

Ammonia combines with extreme rapidity with water, the easier as the water is colder. Heat is given out at the same time. Ice absorbs this gas with equal facility, and in so doing it appears to melt as fast as if a red-hot iron were applied to it. Sir Humphry Davy's experiments on this subject are useful, and bear the marks of every practicable degree of accuracy.

This chemist found that 50 grains of water absorbed 17 grains of gaseous ammonia (rather more than a third of its weight; and according to the calculation given above, nearly 463 times its bulk); and by this absorption the bulk of the liquid was much increased, or in other words its specific gravity was diminished. Therefore the levity of such a solution is in direct proportion to its strength of alkaline impregnation. By calculation from two extreme terms, Sir Humphry Davy gives the following table of specific gravity of liquid ammonia, corresponding with the respective quantities of alkali and water in the solution. As this preparation is in constant use, we shall give the table, which may be of service in ascertaining its strength, and regulating the price which it should bear. The temperature is assumed to be 52°, but the changes in specific gravity from 40° to 65° are not materially different.

Spec. gr.		Ammonia.		Water.

Liquid ammonia (the aqua ammoniæ puræ of the Pharmacopœias) is actually prepared from the same materials in two ways; in one, the liquid itself is distilled; in the other, the gas is received in water, and there absorbed. The former is the oldest method, and is still practised very largely. It is the following: slack two pounds of well-burnt quick lime with one pint of water; when thus reduced to powder, mix it with sixteen ounces of muriated ammonia already in powder, put it into a retort, add five pints ot cold water, and lute on a receiver capable of being kept extremely cool, if possible surrounded with ice. Then distil off, with a moderate heat, twenty ounces of the liquid, which will be the liquid ammonia, or caustic volatile alkali. It is to be observed that the ammonia is so much more volatile than water, that the whole of it comes over with the first pint or pint and a quarter of water, so that no advantage whatever is gained by continuing the distillation any longer. The rest of the water serves to keep the residue sufficiently liquid to be readily taken out of the retort. Twice as much lime as necessary is employed; but this excess serves to keep down any carbonic acid that might otherwise rise. The specific gravity of the liquid thus prepared is about .936, and contains about 17 per cent. of ammonia. The process should be conducted slowly, and the receiver kept very cool, or else the water will again part with the alkali; and this latter, escaping in the form of gas, may burst the vessels if tight, or run to waste if open.

The other method, which is neater and probably better in every respect, is to receive the gas from the lime and sal ammoniac in a known quantity of water, which will absorb it till saturated. No more water, therefore, should be added to the materials than is just sufficient to slack the lime (about half its weight); and to make a strong solution as can conveniently be kept in a summer heat, as much water should be employed to absorb the ammonia as the weight of the muriated ammonia put into the distilling vessel. This last, instead of a wide neck, should terminate in a bent tube, plunged to the bottom of the water, and an apparatus similar to that of Woulfe's to prevent absortion. If the receiving bottle is surrounded with ice, the retort may be heated pretty rapidly.

As this liquid speedily absorbs carbonic acid from the air, it should be kept in well-closed bottles. The effect of heat upon it has been already mentioned to be the entire expulsion of the ammonia in the form of gas, and nothing but pure water is left. The effect of cold is singular. If cooled very low, ammonia loses much of the pungency of its smell (the alkali not being then so easily given off); at last, at the temperature of freezing mercury, (.40), it begins to crystallize in brilliant flexible needles; or if more hastily cooled to this intense degree, or even still lower, it becomes grey, semi-transparent like glue, or like silex in its gelatinous-precipitate form, and with scarcely any scent.

Many other liquids will absorb ammoniacal gas. Alcohol does it with great ease, and appears but little altered by it. We shall now relate some of the numerous experiments that incontestibly prove that ammonia is a compound substance, which are both analytical and synthetical, this alkali being decomposed in a variety of processes, and in a few, being formed by direct union of its constituent parts.

Dr. Priestley's experiments are among the first in the decomposition of this alkali. On passing the electric spark through this gas, he found it to be permanently enlarged after every shock, and when water was admitted, just so much remained unabsorbed as had been added by the explosions. The air was now strongly inflammable, detonating when mixed with common air, as violently as the inflammable air from metals. The colour of the electric spark was red in this air, as in hydrogen. The extent of dilatation, Dr. Priestley found to be about three times the original bulk of the ammoniacal gas, and when at its extreme degree, no portion of the electrified air was now absorbed by water. He afterwards found that mere heat would produce a similar effect, though less perfectly, for on pass-

ing alkaline air through a red-hot tube, part of it was changed to inflammable air, and part went through unaltered. Inflammable air, or hydrogen, is therefore thus proved to be one constituent of ammonia. The other is detected by the following beautiful and simple experiment. Having previously found that the oxides of lead were revived when heated in inflammable air, Dr. Priestley tried the same with ammoniacal gas, and found that massicot (an oxide of lead) was thereby reduced to reguline lead, with a certain diminution of the air, but not so complete as when hydrogen alone was employed; for the alkaline air, after it would reduce no more of the metal, left a large residue, which Dr. Priestley, to his surprise, found to be nitrogen or azotic gas. Red mercurial oxide was in like manner reduced in alkaline air; water was generated in a very sensible quantity, and the residue, as before, was azotic, mixed with some oxygen gas from the mercurial oxide. These experiments of the electrization of ammonia, and of the reduction of metallic oxides, have been confirmed by many other chemists.

The partial decomposition of volatile alkali by metallic oxides did not escape the acute observation of Scheele. This eminent chemist observed that liquid ammonia, when suffered to remain in contact with oxide of manganese and nitrous acid, was entirely decomposed, and furnished an elastic gas, whilst the oxide of manganese was so far reduced to the metallic state as to become soluble in the nitrous acid. The ammonia, therefore, furnished hydrogen to the oxygen, to seperate it in the form of water from this metal, and the other part of the ammonia, the nitrogen escaped in a gaseous form; thus convincing by its composition.

But the most accurate and convincing experiments on this alkali were undertaken by M. Berthollet, on the facts discovered by Priestley and Scheele. M. Berthollet first ascertained that on the distillation of nitrous ammonia more water was produced than belonged to the crystallization of the salt, and that the source of this water was the mutual decomposition of the acid and the alkali; the former supplying the oxygen, and the latter the hydrogen.

M. Berthollet also repeated the experiment of the reduction of metallic oxides on ammonia. Oxide of copper dissolved in this alkali, evaporated to dryness, and afterwards strongly heated, became completely reduced; water was formed, and nitrogen gas given out, together with some ammonia that had escaped decomposition. Hence M. Berthollet beautifully explained the detonation of fulminating gold, and even confirmed it by actual experiment in close vessels. This preparation is oxide of gold combined with ammonia; when heated it detonates vehemently, the gold is reduced, water is suddenly formed, and nitrogen gas given out.

Another singular phenomenon, also observed by M. Berthollet, is explained by the decomposition of ammonia. When oxymuriatic acid is mixed with liquid ammonia, a strong effervescence takes place, though the alkali contains no carbonic acid; a gas is given out, and the acid immediately loses its characteristic properties, becoming simple muriatic acid.

This is beautifully explained by the decomposition of ammonia, the hydrogen of the alkali uniting with the excess of oxygen in the acid into water, and the nitrogen of the alkali appearing uncombined in a gaseous form; for the effervescing gas when examined is found to be azotic. A crowd of interesting experiments, subsequent to these above mentioned, come in confirmation of this hypothesis of the decomposition of ammonia. M. Fourcroy, on passing the oxymuriatic acid gas into liquid ammonia, obtained a large quantity of azotic gas, which was collected in the pneumatic trough. On adding ammoniacal gas to oxymuriatic gas, a white flame was produced, and water was immediately seen trickling down the sides of the vessels.

The same chemist has also pursued the experiments with ammonia and metallic oxides. Liquid ammonia added to nitrate of mercury in solution, precipitates the metal black, and nearly metallic, and azotic gas is given out. The same takes place more strikingly with liquid ammonia, and red mercurial oxide in powder. A strong effervescence of azotic gas takes place, the oxide turns first white, then black, and on being moderately heated becomes mostly running mercury. The black oxide of manganese, moistened with ammonia in like manner, effervesces slightly even at a cold temperature, the metal is particularly reduced and becomes grey, and azotic gas is formed.

Nitrate of iron treated with ammonia, is equally reduced to the state of the least oxydation, and the precipitate is the black oxide of iron.

Many of the neutral ammoniacal salts when strongly heated, are partly sublimed and partly decomposed. The nitrate of ammonia has been already mentioned. Mr. Chenivix found that the sulphate of ammonia being distilled, gave out first the water of crystallization, then part of the salt sublimed unaltered, after which came over sulphureous acid and azotic gas, which continued to the end of the process.

The alkali of muriate of ammonia, though not easily destructible by mere heat, is entirely decomposed by the nitric acid. Mr. Woulfe, by distilling one pound of nitric acid from four ounces of muriate of ammonia, found the acid to act with great vehemence on the salt, and the whole contents of the retort were distilled over in a liquid form, in which no trace of undecomposed ammonia could be detected. The nitric acid was also in part decomposed, and much azotic gas, mixed with some oxygen, was given out in the process.

It often happens that in the decomposition of the alkali, the nitrogen, which is one of the constituents of ammonia, instead of being given out in the form of gas, enters into new combinations, particularly with oxygen when present in excess, and forms nitrous acid. The particulars of this singular conversion will be given under this article, but it may be mentioned here, that Dr. Milner produced this acid by passing ammonia through heated oxide of manganese; Fourcroy the same, by ammonia and sulphate of mercury; and Proust the same, by strongly heating a mixture of ammoniacal gas with an excess of oxygen. If a smaller quantity of oxygen be used, the product of the gases, after detonation in a high heat, is merely water and azotic gas.

We have now to mention some of the experiments in which ammonia is produced by a mixture of its constituent parts.

Animal putrefaction, and the disorganization of all animal and many vegetable substances by fire, are processes of this kind, that are perpetually going on; for in neither instance can ammonia be traced in the substance in any notable quantity, before putrefaction or combustion. But chemistry furnishes us with more direct experiments.

An ammoniacal smell has often been observed accidentally by several chemists, where it was not expected; and more particularly in experiments with nitrous gas or acids, and various metallic oxides. This was noticed by Dr. Priestley, in a solution of nitrated copper mixed with iron filings, which had long stood together. Mr. Hauffman, of Colmar, has shown the same production of alkali, on mixing nitrous gas with the precipitate from acetate of iron. In this case the nitrous gas is rapidly absorbed by the iron precipitate, and at that time such an interchange of principles takes place, that a small portion of nitrate of ammonia is formed in the mixture. On adding lime or caustic potash, the ammonia is expelled and becomes sensible to the smell. A like production of volatile alkali always takes place when the green sulphate of iron is saturated with nitrous gas. This is a curious fact, and depends on very complicated affinities. It will be sufficient to observe in this place, that the azote of the ammonia is provided for in the nitrous gas, and the hydrogen in the decomposed water of the solution. Dr. Austin's experiments on the formation of ammonia are highly interesting. Dr. A. found that no mixture of the two constituents, hydrogen and azote, when both in a gaseous form, could be brought to unite into ammonia, either by mixture in any proportion, or by any third addition. Even when the two gases were the identical parts of a given quantity of ammonia, decomposed by electricity, they could not again be re-united in their alkaline form. Dr. A. attributes this, probably with reason, to the great difference of specific gravity between the two gases, and hence he was led to attempt an union between the two, by putting the hydrogen in contact with azotic zas at the instant of its formation, before it had perfectly assumed the form of hydrogen gas, or as it is termed in its nascent state. This method succeeded. Iron filings, which are known to yield hydrogen soon after mixture with water, were moistened and inclosed in an atmosphere of azotic gas. In about twenty-four hours ammoniacal gas was detected, by the usual test of changing to green a piece of blue-stained paper which was suspended in the vessel. The green of nitrated copper on paper was also changed to blue by the same process in a few days. The same generation of ammonia took place in a few hours when nitrous gas was substituted for the azotic. On the other hand the same change occurred, though in a longer time, when common air was used instead of the azotic. Hence it would follow that a small portion of ammonia is always produced whenever iron rusts in the open air, or generally by every natural process which evolves hydrogen.

In the following simple experiment the volatile alkali is produced immediately in a very sensible quantity. Pour some moderately-strong nitrous acid upon an ounce or two of tin filings, sufficient to moisten them completely, and stir them together; the action will be immediate and vehement, and copious fumes of nitrous gas will arise; a very short time afterwards add some lime or dry caustic alkali, rub them together, and a very pungent smell of ammonia will be given out. In this experiment the ammonia which is formed from the decomposition both of nitrous acid and of water, first unites with another part of the acid, forming nitrate of ammonia, which might be procured as such from the mixture. Then, on adding the lime, this newly-formed salt is again decomposed, and the volatile alkali is expelled in its gaseous form. Zinc filings, moistened with nitrated copper, and mixed with lime, equally give out ammonia.

The method which has been pursued by M. Berthollet and succeeding chemists, of ascertaining the relative proportions of the two ingredients of ammonia (and indeed the only one practicable), has been first to resolve ammoniacal gas into its constituent parts, hydrogen and azotic gases (for which electricity offers a certain but tedious agent), and then to abstract the hydrogen by detonation with oxygen in Volta's eudiometer. The perfect resolution of the ammonia after electrization over mercury, is known by the enlargement ceasing, and by the electrized gas being now entirely unabsorbed when water is thrown up to it. In the subsequent detonation of the hydrogen (in which an excess of oxygen thould be employed) a great portion of the gas disappears; which loss, as it is accounted for by the production of water, must be estimated according to the known proportions in which hydrogen and oxygen constitute this fluid. The remaining gas (allowing for the excess of oxygen employed) is the azote, the other constituent of the ammonia. In this manner M. Berthollet estimates the composition of ammonia to be 121 by weight of azote, and 29 of hydrogen; supposing too that the comparative specific gravity of the former to the latter is as 11 to 1.

Sir Humphry Davy in his experiments decomposed his ammonia by transmission through a red-hot tube of green glass; after which he estimated the hydrogen and azote in the manner above mentioned, and the result coincided almost exactly with that of M. Berthollet.

An approximation to the same result is afforded by calculation from the known specific gravities of all the airs concerned in these experiments. According to Mr. Kirwan, 100 cubic inches of alkaline air weigh 18.16 grains, of azotic air weigh 30.535 grains, and of hydrogen gas weigh 2.613 grains. M. Berthollet reckons that 1.7 cubic inches of ammonia expands by electrization to 3.3, and consequently 100 cubic inches of the electrized air now weigh only 9.355 grains; and by subsequent calculation, Dr. Austin found that a mixture of this specific gravity is formed by 121 grains of azote, and 20 of hydrogen.

Ammonia combines with great ease with all the acids, forming neutral salts, which will be described under the respective acids. Its affinity for acids is weak compared to that of the other alkalies and many of the earths. It is a remarkable property of this alkali, that in many instances when added to earthy or metallic salts, where its affinity to the acid is on the whole greater than the basis already combined, it only partially decomposes them, uniting with the remainder of the salt into a triple compound, sometimes crystallizable, consisting of the acid, the earth, or metallic oxide, and ammonia. It is of importance to be aware of this in chemical analysis. The affinity of magnesia, for example, is so nearly the same as that of ammonia to acids, that ammoniaco-magnesian triple salts are constantly occurring when the three substances come together.

The frequent decomposition of ammonia upon metallic oxides, reducing them from the highest state of oxydation to the lowest, or even to the reguline state, has already been mentioned, when describing the

facts that prove the decomposition of this alkali. It also simply dissolves other metallic oxides, as copper, cobalt, zinc, nickel, tungsten, &c. Some of these compounds are crystallizable.

When ammoniacal gas is mixed with some of the gaseous acids, the carbonic or muriatic for example, a most beautiful phenomenon occurs: the two gases instantly on mixture form a dense white cloud, totally lose their gaseous form, and condense into minute flakes of the dry crystallized ammoniacal salt, so that, if pure, not an atom of gas is left in the vessel in which they are mixed. A rapid and complete absorption therefore is the consequence, and this is attended with a very sensible evolution of heat.

This circumstance affords a very delicate test of ammonia; for if any of the alkaline gas is given off from any substance (suppose an uncorked bottle of liquid ammonia), and a glass rod, straw, or any thing of the kind be only moistened with muriatic or nitrous acid, and held in the ammoniacal atmosphere, the alkali floating in the air will immediately be detected by the thick white cloud of nitrate, or muriate of ammonia, which will be seen to hover round the acid. This test is even more delicate than the smell. The caustic powers of the volatile alkali are much inferior to those of the two fixed. It does not readily corrode animal matter. With oil it unites readily to a certain degree, but not so firmly and perfectly as the fixed alkalies.

Sulphur may be made to combine with ammonia by distillation. Some interesting products are the result.

The constant tendency of ammonia to assume the gaseous state, in a very moderate heat, forms a considerable obstacle to its union with many bodies with which the fixed alkalies may be made to combine; of course there can be no such substance as an ammoniacal glass, it being impossible to combine it with the materials necessary to the formation of that substance.

Ammonia in its caustic state is used only in medicine and the laboratory. Ammoniacal gas is one of the best correctors to the dangerous suffocating properties of the vapour of oxymuriatic, and probably of other acids. In the event of such an accident, the speediest method will be to mix quick lime and muriated ammonia with a little water, and to place the vessel containing it on the floor, as near to the feet of the sufferer as can be borne with security, so as to allow him to inhale cautiously some of the ascending ammoniacal gas, which will be given off in great abundance.

Ammoniacal gas is detected, as we have before mentioned, by giving a dense white fume with muriatic acid vapour. It is known to be pure when it is totally and instantly absorbed by water. This test is in general sufficient, for the other rapidly absorbable gasses are the aeriform acids, which cannot remain in a gaseous state along with ammonia. If a small admixture of sulphureted hydrogen gas be suspected, the test of acetate of lead may be used, which will be blackened by water that has absorbed this gas, but not by liquid ammonia. The solution of ammonia in water is known to be perfectly deprived of carbonic acid when it gives no effervescence with acids, no cloudiness on mixture with strong alcohol, and particularly when it does not alter the transparency of a solution of pure lime (calcareous spar or Carrara marble) in the nitrous, muriatic, or acetic acids. This last, which is a most delicate test, should be made in a well-corked bottle; for though pure ammonia will not precipitate lime, carbonate of ammonia will do it very readily; and the alkali, if exposed to the air, will speedily absorb from it sufficient carbonic acid to render this test fallacious. If muriate of ammonia is accidentally mixed with liquid ammonia in the process of distillation, the presence of the muriatic acid is thus detected: saturate part of the liquor with pure distilled vinegar, and add to it a few drops of nitrated silver, a white precipitate of luna cornea will then indicate the muriatic acid, for nitrate of silver is not clouded by pure acetate of ammonia. We may add, that in the analysis of any substance supposed to contain an ammoniacal salt, this alkali is best expelled by adding lime to the substance to be analyzed, and distilling the whole in a close vessel. The whole of the ammonia then comes over with the very first products, and if condensed by a little water in a cool receiver, it is thus obtained in a concentrated state convenient for further examination.

The affinities of ammonia are the same as those of potash and soda in the moist way, but the tendency of the volatile alkali to gasification on the application of heat is so strong as to throw some uncertainty on its relative affinities, even at a moderately elevated temperature.

Ammoniacal Preparations, in *Pharmacy*. There are several pharmaceutical preparations, into which the volatile alkali, under one form or another, enters as a principal ingredient. Of these the only one in which the alkali is employed in its caustic state, is the aqua ammoniæ puræ (*Pharm. Lond.*), also called caustic spirit of ammonia, or spirit of ammonia with quick-lime (spiritus ammoniæ cum calce viva), the method of preparing which has already been described.

It may be observed, that though it is called a spirit it only consists of water impregnated with pure ammonia through the medium of distillation. The appellation, "with quick-lime," is added to distinguish it from the simple spirit of sal-ammoniac, which is prepared (from the distillation of muriate of ammonia in both cases, but) with chalk, and is therefore not caustic, but carbonated, and effervesces with acids.

The several preparations of the carbonate of ammonia employed in medicine, will be mentioned more particularly under that article and *Hartshorn*. The principal are the prepared ammonia, ammonia preparata (*Pharm. Lond.*), sal volatile, salt of hartshorn, which is the solid carbonate of ammonia in its pure state, prepared for the most part by sublimation of some of the neutral ammoniacal salts with chalk.

Aqua ammoniæ (*Pharm. Lond.*), or spirit of sal-ammoniac, is prepared by distilling muriate of ammonia, chalk, and water; and is in fact nothing but a solution of carbonate of ammonia in water, effected by the medium of distillation, and perhaps containing a small portion of the caustic ammonia, where the chalk is not perfectly mild. Sometimes this liquor is prepared with pearlash, or carbonate of potash instead of chalk. The effect will be the same upon the ammoniacal liquor, only when the pearlash is used, as it is always in a semi-caustic state, it will render the volatile alkali somewhat less carbonated.

Spiritus ammoniæ (*Pharm. Lond.*), spiritus salis ammoniaci dulcis sive vinosus. This differs from the preceding in being a real distilled spirit, as proof

spirit of wine is the menstruum employed for the alkali instead of water. The term spirit is therefore, in the present *London Pharmcopœia*, very properly confined to the ammoniacal preparations where spirit of wine is employed; and the term, water of ammonia, is adopted where this liquid is the solvent for the alkali.

The true spirit of ammonia is made the basis of several powerful compound preparations, in which either an aromatic oil and water or a fetid gum is united with the alkaline spirit, according to the intention which it is to answer. Of the former kind is the spiritus ammoniæ compositus, or volatile aromatic spirit, prepared by dissolving bergamotte essence and oil of cloves in the alkaline spirit (either with or without the help of distillation); of the latter is the spiritus ammoniæ fœtidus, in which a certain quantity of assafœtida is dissolved in the spirit. The ammoniacal spirit is likewise made the basis of some tinctures, instead of simple spirit of wine, where the operation of the volatile alkali properly combines with that of the gum or resin dissolved in the tincture.

Amplitude, in *Astronomy*, is an arch of the horizon, intercepted between the true east or west point, and the centre of the sun, or a star, at its rising or setting, so that the amplitude is of two kinds; ortive or eastern, and occiduous or western. These are also called northern or southern, as they fall in the northern and southern quarters of the horizon; and the complement of the amplitude, or the distance of the point of rising or setting, from the north or south point of the horizon is called the azimuth. To find the sun's or star's amplitude, either rising or setting, by the globe, see Globe.

To find the sun's amplitude trigonometrically, having the latitude and the sun's declination given. Say, as the cosine of the latitude is to the radius, so is the sine of the sun's or star's declination to the sine of the amplitude. Suppose, e. gr. the latitude to be that of London, viz. 51° 32′, and the declination 23° 28′; then cosine 51° 32′, or 9.7938317 : rad. or 10.0000000 :: sine of declination 23° 28′, or 9.6001181 : 10.0000000 + 9.6001181 — 9.7938317 = 9.8062864, or sine of the amplitude, or 39° 48′; and this is of the same name with the given declination, viz. north, when the declination is north, and south when the declination is south.

Amplitude, *Magnetical*, is an arch of the horizon, contained between the sun or star at its rising or setting, and the magnetical east or west point of the horizon, indicated by the magnetical compass, or the amplitude or azimuth compass; or it is the difference of the rising or setting of the sun, from the east or west points of the compass. To ascertain this, place the compass on a steady place, from which the horizon may be clearly seen, and looking through the sight-vanes of the compass, turn the instrument round, till the centre of the sun or other celestial object may be seen through the narrow slit which is in one of the sight-vanes, exactly in the thread which bisects the aperture in the other sight-vane; and when the centre of the celestial object, whether rising or setting, is just in the horizon, push the stop in the side of the box so as to stop the card, and then read the degree of the card which stands just against the fiducial line in the box; and this gives the amplitude required. In this operation allowance must be made for the height of the observer's eye above the level of the sea. The difference between the magnetical amplitude, thus observed, and the true amplitude, obtained by the last article, is the variation of the compass.

Analysis, in *Philosophy*; the mode of resolving a compound idea into its simple parts, in order to consider them more distinctly, and arrive at a more precise knowledge of the whole. It is opposed to *synthesis*, by which we combine and class our perceptions, and contrive expressions for our thoughts, so as to represent their several divisions, classes, and relations. *Analysis* is regressive, searching into principles; *synthesis* is progressive, carrying forward acknowledged truths to their application.

Analysis, in *Mathematics*, is in the widest sense the expression and developement of the functions of quantities by calculation. There are two ways of representing the relations between quantities, by construction, and by calculation. Pure geometry determines all magnitudes by construction, that is, by the mental drawing of lines, whose intersections give the proposed quantities; analysis, on the contrary, makes use of symbolical formulæ, called *equations*, to express relations. In this widest extent of the idea of analysis, algebra, assisted by literal arithmetic, appears as the first part of the system. Analysis, in a narrower sense, is distinguished from algebra, inasmuch as it considers quantities in a different point of view. While algebra speaks of the known and unknown, analysis treats of the unchanging or constant, and of the changing or variable. The algebraic equation, $x^2 + a\,x - b = 0$, for example, seeks an expression for the unknown x by means of the known a and b; but the analytical equation, $y^2 = ax$, expresses the law of the formation of the variable y, by means of the variable x, together with the constant a. In its application to geometry, analysis seeks by calculation the geometrical magnitudes for an assumed or undetermined unit. The analysis of the ancients was exhibited only in geometry, and made use only for geometrical assistance, in which it is distinguished from the analysis of the moderns, which, as before said, extends to all measurable objects, and expresses in equations the mutual dependence of magnitudes. But analysis and algebra resemble each other in this, that both reason in a language, into the expressions of which certain conditions are translated, and then, according to the rules of the language, are treated more fully in order to arrive at the result. Analysis, when considered in this light, appears to be the widest extent of the province of this language. Analysis, in the more limited sense, is divided into lower and higher, the bounds of which however run very much into one another. While we comprise in lower analysis, besides arithmetic and algebra, the doctrines of functions, of series, combinations, logarithms, and curves, we comprehend in the higher the differential and integral calculus, which are also included in the name *infinitesimal calculus*; the first of which the French consider as belonging, in a wider sense, to the *théorie des fonctions analytiques*.

Anatomy. This term, strictly speaking, implies but the cutting to pieces, or artificial separation of the different parts of any body. We purpose however in the present article, in the first instance, to give a brief history of the science in its general connection with the healing art, and then to describe in a systematic, yet concise way, the general mechanism of the human structure.

Anatomy, as a science, does not appear to have been of such general antiquity as its importance would lead us to suppose. Neither the Jews or Phoenicians paid much attention to it. We find by the writings of Plato, that that distinguished philosopher and his scholars had carefully considered the human body, both in its organization and functions; and though they had not arrived at the knowledge of the more minute and intricate parts, which required the successive labour and attention of many ages, they had formed very noble and comprehensive ideas of the subject in general. The anatomical descriptions of Xenophon and Plato have had the honour of being quoted by Longinus as specimens of sublime writing; and the extract from Plato is still more remarkable for its containing the rudiments of the circulation of the blood. "The heart," says Plato, "is the centre or knot of the blood-vessels; the spring or fountain of the blood, which is carried impetuously round; the blood is the *pabulum* or food of the flesh; and for the purpose of nourishment, the body is laid out into canals, like those which are drawn through gardens, that the blood may be conveyed, as from a fountain, to every part of the pervious system."

Hippocrates was nearly contemporary with the great philosophers of whom we have been speaking, and flourished about 400 years before the Christian era. He is said to have separated the professions of philosophy and medicine, and to have been the first who applied to the latter alone as the business of his life. He is likewise generally supposed to have been the earliest writer upon anatomy, as we are unacquainted with an express work of any previous author upon that subject, and as the first anatomical dissection which has been recorded, was made by his friend Democritus of Abdera. If, however, we read the works of Hippocrates with impartiality, and apply his accounts of the parts to what we now know of the human body, we must allow his descriptions to be imperfect, incorrect, sometimes extravagant, and often unintelligible, those of the bones alone excepted. He seems to have studied this portion of the frame with more success than any other, probably because, as he tells us, he had an opportunity of seeing a human skeleton.

After the death of Hippocrates, the study of anatomy was prosecuted with zeal at Athens by the most eminent philosophers of the period, among whom we find Aristotle and Theophrastus. But few of the writings of the former were made public during his lifetime; he affected to say that they would be unintelligible to those who had not heard them explained at his lectures; and, except the use which Theophrastus made of them, they were lost to the world for nearly two hundred years; and at last came out defective, and corrupted by men who, without proper qualifications, presumed to correct and supply what was lost. From the time of Theophrastus, the study of natural knowledge at Athens began to decline, and the reputation of the Lyceum and Academy was almost confined to the studies which are subservient to oratory and public speaking.

When Athens began to lose its celebrity as a medical school, that of Alexandria increased and flourished. The first Ptolemies, both from their love of literature, and a desire to give true and permanent dignity to their empire and to Alexander's favourite city, established a splendid school in the palace itself, with a museum and a library, which has been considered as the most famous in the world. Anatomy, with the other sciences, was publicly taught; and the two most distinguished professors were Erasistratus, the pupil and friend of Theophrastus, and Hierophilus. Their voluminous works are all lost; but they are repeatedly quoted by Galen. These professors were probably the first who were authorized to dissect human bodies; a peculiarity which marks strongly the philosophical magnanimity of the first Ptolemy, and fixes a great era in the history of anatomy. And it was no doubt from this particular advantage which the Alexandrian philosophers had above all others, that their school not only gained, but for many centuries preserved, its great reputation for medical science. Ammianus Marcellinus, who lived about 650 years after the schools were established, says "they were so famous in his time, that it was enough to secure credit to any physician, if he could say that he had studied at Alexandria."

The first Greek physician established in Rome was Archagathus, who flourished about 220 B. C., and was banished the city on account of the severity of his operations. About a century after Archagathus, and in the time of Pompey, we find Asclepiades, who had attained such high reputation as to be ranked in the same class with Hippocrates. He seemed to have some notion of the air in respiration, acting by its weight; and in accounting for digestion, he supposed the food to be no farther changed than by a comminution into extremely small parts, which being distibuted to the several portions of the body, assimilated itself to the nature of each. It is curious, that about this period, Cassius, a disciple of Asclepiades, accounted for the right side of the body becoming paralytic on injuring the left side of the brain, in the same manner as many modern writers have, viz. from the crossing of the nerves from the right to the left side of the brain.

From the time of Asclepiades to the second century, physicians seem to have been greatly encouraged in Rome, and in the writings of Celsus, Rufus, Pliny, Cœlius, Aurelianus, and Aræteus, we find several anatomical observations, which are however mostly very superficial and inaccurate. Towards the end of the second century lived the celebrated Claudius Galenus of Pergamus, whose name is so well known in the medical world. He applied himself particularly to the study of anatomy, and rendered greater services to the science than all who preceded him. He seems however to have been at a great loss for human subjects to operate upon; and therefore his descriptions of the various parts of the body are mostly taken from the inferior animals. His works contain the fullest history of anatomy, and the most complete system of the science to be met with any where before him, or for several centuries after.

About the end of the fourth century, Nimesius, Bishop of Emissa, wrote a treatise on the nature of man, in which it is said were contained two celebrated modern discoveries; the one the uses of the bile, boasted of by Sylvius de la Boe; and the other, the circulation of the blood. This last, however, is proved by Dr. Friend, to be falsely ascribed to this author.

The Roman empire now began to suffer from the inroads of various barbarous tribes, and learning declined; and when the empire was totally overwhelmed, every appearance of science was almost extinguished in Europe. The only remains were to

be found amongst the Aarbians in Spain and in Asia. The Saracens, who came into Spain, destroyed at first all the Greek books which the Vandals had spared; and though their government was a constant struggle with the Christian powers for many centuries, till they were driven out, they thus acquired a taste for learning which they conveyed to their countrymen in the east; several of their princes encouraged liberal studies; public schools were set up at Cordova, Toledo, and other towns, and translations of the Greeks into Arabic were universally in the hands of their teachers.

By this means was the learning of the Grecians transferred to the Arabians, who, however, though they had so good a foundation to build upon, were satisfied with commenting upon Galen, and seem to have practised no dissections on human bodies. In the tenth century, Constantine, a native of Bagdad, brought with him the Arabian doctrines on medicine to the Solernitarnian school in Sicily; and here anatomy began slowly to revive. In the fourteenth century, Mundinus dissected human bodies in Italy, and by degrees other nations acquired that useful art.

Anatomical knowledge, on its revival in Europe, was greatly promoted by the exertions of eminent painters, who were early and accurate dissectors, correctly delineating the muscles, after they had removed the integuments which covered them. Raphael, Titian, and Leonardo da Vinci were famous for their anatomical skill, which is indeed sufficiently evident in their paintings. A number of sketches, designed as studies by Leonardo da Vinci, are still extant in his Majesty's collection of drawings, and are spoken of by Dr. Hunter in the most encomiastic terms. Albert Durer, who is also ranked by Haller among the restorers of anatomy, published many plates representing the proportions and gestures of the human form and countenance.

When the Turks had subdued Greece, the inhabitants fled for safety to the western nations of Europe, bringing with them the Grecian authors on medicine, and translating them; and the invention of printing, which happened about the same time, greatly favoured their dispersion throughout Europe. An opportunity was now afforded of becoming acquainted with the writings of Galen and the ancients, and by these means, of arriving at the source of that knowledge which they had hitherto obtained only through the channel of the Arabian physicians. The superiority of the former was soon discovered, and the opinions of the Grecian writers were considered, even in anatomy as incontrovertible.

In the middle of the sixteenth century several eminent anatomists flourished, among whom were Sylvius and Vesalius, Fallopius and Eustachius. Sylvius taught anatomy in Paris in 1532. Vesalius was the first who recommended the injection of coloured fluids into the vessels of the body, in order to facilitate the labour of minutely tracing them. Whilst he was a student in college, he pursued anatomical inquiries with great ardour and assiduity, and published some of his discoveries before he was twenty-five years of age, and seven books on the anatomy of the human body before he was twenty-nine, A. D.1542. These books contain great discoveries, and in many circumstances correct the ancients. But although they have entitled their author to the gratitude of posterity, they procured to him scarcely any thing but animosity from his contemporaries. At that time the authority of Galen was held in high veneration; and when Vesalius exposed his errors, the hatred of all seemed turned against him. But knowledge was increased by these contentions; all parties were obliged to refer for the materials and support of controversy, to the book of nature, which they could not consult without receiving instruction. Even Vesalius was detected, in some instances, in the error with which he charged Galen—that of describing the anatomical structure of the human body from the dissection of brutes. In 1561, Fallopius, in Italy, published his *Observationes Anatomicæ;* he was an indefatigable anatomist, and made great discoveries. About the same time Eustachius made himself conspicuously eminent by promoting anatomical knowledge. He seemed calculated for subtle investigations; he drew many figures of the human body, and engraved his own plates, the accuracy of which cannot fail of exciting surprise in an anatomist of the present day. When the labours of these eminent men had, as it were, smoothed the path, anatomy was taught with a moderate degree of correctness and minuteness in the different schools of Europe. "Shortly after," as Haller has observed, "the different nations being engaged in war, the same attention was not paid to public institutions and dissections. Anatomists had therefore recourse to the examination of the bodies of brutes, from which they derived many important discoveries."

Early in the seventeenth century the circulation of the blood was discovered by Dr. Harvey, who was born at Folkestone in Kent, on the 2d of April, 1578.

Dr. Harvey studied at the University of Cambridge, and afterwards travelled through France and Germany to Padua in Italy, where he was honoured with the degree of Doctor of Medicine. On his return to England, he became a graduate in medicine at Cambridge, and afterwards settled in London; and in the year 1615 was made a Fellow of the London College of Physicians. In the following year he read a course of lectures, developing the circulation of the blood, and with such accuracy that no improvement in it has been made, although the discovery took place two hundred and fifteen years ago.

It is a surprising coincidence, but not more surprising than true, that when one discovery has been made another has quickly followed; and in this place it is strikingly exemplified by Asellius discovering the lacteals, which Pecquect traced to the thoracic duct, and thence to the left subclavian vein. About thirty-eight years after Harvey had discovered the circulation of the blood, Rudbeck and Bertholin discovered the tubes called lymphatics. This discovery was not made from the joint, but individual, efforts of those anatomists, each being unacquainted with the other's discovery until after it had been published, which occurred about the same time. The description which Bertholin gave of the use of this system of vessels was more generally approved than that given by Rudbeck, consequently his merits were duly appreciated. Although Bertholin's description was superior to that of his contemporary Rudbeck, still this explanation was very imperfect, and became the subject of Glisson's consideration, from whom it received considerable improvement. The discovery of the lymphatic system left little to be accomplished by anatomists of the seventeenth, eighteenth, and present centuries, further than confirm what had been previously discovered, and direct their attention to a further and correct knowledge of the functions

and use of the various parts of the human body. Amongst the vast nnmber who have thrown considerable light upon anatomy, and particularly physiology, the following names stand prominently conspicuous, viz. Albinus, Cooper, Highmore, Cheselden, Lewenhoeck, Malpighi, Willis, and Winslow, in the seventeenth century; and in the eighteenth, Haller, Morgagui, Scarpa, Soemmering, Monro, Hunter, Cruickshanks, and Bell. Those of the present are Abernethy, Blizard, C. Bell, Bichat, Cooper, Majendie, and Cuvier.

Of the discoveries of these distinguished anatomists and physiologists, full accounts will be given under their distinct departments of science.

The solids consists of fibres or small filaments, which differ in their degrees of hardness or elasticity. They are divided into *integumenta*, the integuments; *ossa*, the bones; *cartilagines*, cartilages; *ligamenta*, ligaments; *membranæ*, the membranes; *vassa*, the vessels; *musculi*, the muscles; *nervi*, the nerves; and *glandulæ*, the glands.

Integuments are the coverings of the whole body, comprehending the *epidermis*, cuticle or scarfskin, which is the outermost; *rete mucosum*, a net-work immediately under the epidermis; *cutis vera*, the real skin, which retains and carries off all the humours of the body; *corpus adiposum, seu membrana adiposa*, the fat, a cellular substance containing an unctuous juice. To the above may be added *capillus*, the hair, which consists of cellular filaments, and is denominated the beard, eye-lashes, &c, according to the place in which it grows (see HAIR); *unguis*, the nails, which are horny substances.

Bones are hard and brittle substances composed of *lamellæ*, or plates lying upon one another, and joined together by transverse fibres. They are covered with an exquisitely sensible vascular membrane, called the *periosteum*, which on the cranium, or skull, is called the *pericranium*. On the surface of the bones are both eminences and cavities. The eminences are called processes, which are of two sorts, namely, the *epiphyses* and the *apophyses*. The *epiphyses*, or *appendices*, are as it were, parts added to the bone; the *apophyses* are set upon or growing to a larger bone, so as to make one, as the natal apophysis.

Processes have different names, according to their figure. A process like a ball is called *caput*, the head; when flattened, *condyle*; the narrow part of the process *cervex*, the neck. A rough process is a tuberosity; and one terminating with a sharp point *corona*, which from its resemblance to other substances is termed mastoid, styloid, anchoroid, spinal, &c. Long ridges are called *spinæ*, the sides of which are *labria*, lips. Processes which form the brims, are *supercilia*.

The cavities and depressions of bones are of two sorts, namely, *glanæ*, which are narrow and shallow, and *botylæ*, which are deep and wide. These are subdivided into pits, or small roundish holes; *furrows* or long narrow channels; *nitches*, or *notches*, small branches in the bones; *sinuosities*, broad but superficial depressions; *fossæ*, large deep cavities; *sinuces*, still larger cavities, within the substance of the bone itself; *foramina*, holes through the body of the bone. The internal structure of the bones consists of cells filled with a fluid fat called marrow, that is contained in follicles.

The juncture of the bones with each other is called articulation, from the *articules*, or joint, at the ends of the bones. This is of two kinds, namely, articulation, properly so called, and *symphysis*, connexion. Articulation and *synarthrosis*, or conjoined articulation. Diarthrosis is subdivided into *enarthrosis*, or the ball and socket, when a large head is received into a deep cavity; *arthrodia*, when a round head is received into a small cavity; *gynglimus*, when a bone receives, and is received into another bone. *Synarthrosis* is the fixing of two bones together without motion, which is of two kinds, namely, by ingrailing, or, as the joiners call it, dovetailing, which is termed *sutura*, a sutura, and by a junction on a more extended surface, which was termed *harmonia symphysis*, or connection, is that species of articulation which takes place through the medium of another body, this is either *synchrondrosis*, a cartilaginous connection; *syneurosis*, a ligamentary connection; *syssarcosis*, a fleshy muscular connection. (See article BONE.)

Cartilages are smooth white substances, which are harder than all the other solid parts of the body, except the bones. They are covered with a membrane called the *perichondium*.

Ligaments are close compacted fibrous substances. The ligaments at the joint are called capsular, because they retain in *capsular*, or bags, the mucilaginous liquor called *synovia*, with which the joints are kept moist.

The *muscle* is a bundle of fleshy or tendinous fibres, consisting of the belly or body, which is the fleshy part; the head and the tail, which are the tendinous parts; these are otherwise called *aponeuroses*, or tendons. The head is fixed on the immoveable joint called the origin, and the tail on the part to be moved, called the insertion. The membranes in which the muscles are inclosed, are called *vaginæ*, or sheaths. As the motions of the human body are performed by means of the muscles, they derive their names mostly from their office, as the *abductor*, *elevator*, *flexor*, *extensor*, &c. (See MUSCLE.) When muscles act in opposite directions, they are called antagonists; but when several concur in the same motion, they are termed *congeneres*.

Membranes are expended substances of a pliable texture, and fitted to serve as coverings for other parts of the body, as the *skin*, *peritoneum*, *plura*, *dura mater*, &c.

The *vessels* are ducts or canals, composed of membranes, the strata of which are called *tunicæ*, or coats. They may be divided generally into blood-vessels and absorbents. Blood-vessels, so called because they serve to circulate the blood through the body, are sither *arteriæ*, arteries, or *venæ*, veins; the former of which convey the blood from the heart, and the latter return it to the heart. (See ARTERY and VEIN.) The arteries have a beating motion, called the pulse, which the veins have not. This pulsation arises from what is termed the *systole* and *diastole*, i. e. the dilatation and contraction of the heart.

Absorbents, so called from their absorbing any fluid, and carrying it to the blood, are the *vasa lactea*, the lacteals; *vasa lymphatica*, the lymphatics; together with their common trunk, the lacteal sac and duct. The lacteals absorb the chyle, and the lymphatics the lymph. The lacteal sac, or *receptaculum chyle*, serves, as the name denotes, to retain the chyle; and sends it by the thoracic duct through the whole body. The lymphatics, with the lacteals of the intestines, form what is called the absorbent system. Most vessels are parted off into branches, which are again split

into smaller branches or ramifications, the last or smallest extremities of which are termed *capillary*.

Nerves are long white medullary chords, springing from the *cerebrum* or brain and spinal marrow, whence they are generally distinguished into the *cerebral* and *spinal nerves*. The cerebral are subdivided into the *olfactory, optic, auditory*, &c. nerves, according to their use. (See NERVE.) They go on in *bundles* or *pairs*, and are afterwards distributed into *branches, ramifications*, and *filaments*, over every part that is endowed with sensibility. In several places the nerves communicate with each other, which communication is called a *plexus*; in other places they unite into knots called *ganglions*.

Glands are secretory vessels, composed of all the different sorts of vessels inclosed in a membrane, and serving to secrete some fluid. As to their fabric, they are *conglobate* or *simple, conglomerate* or *compound*. As to their contents, *mucous, sebaceous, lymphatic, salival, lachrymal*, &c.

The *fluids* come next in order. Under this head we may place those humours or juices which serve either to sustain life or preserve the frame in a healthy state. The principal of those are *sanguis*, the blood; *chylus*, the chyle; *lympha*, the lymph; and *bilis*, the bile.

Blood is a red homogeneous fluid, of a saltish taste, a somewhat urinous smell, and glutinous consistence, which circulates in the heart, arteries, and veins.

Chyle, a milk-like liquor, secreted in the lacteal vessels, by digestion, from the chyme or indigested mass of food that passes from the stomach into the duodenum. The chyle is that fluid substance from which the blood is formed.

Lymph, a liquid contained in the lymphatic vessels has a fatuous smell, no taste, and a crystalline colour; its use is to return the superfluous nutritious jelly from every part, and to mix it with the chyle in the thoracic duct, for the purpose of furnishing nutriment to the animal.

Bile, a bitter fluid secreted in the glandular substance of the liver. In a healthy state it is a yellow-green colour, and of the consistency of thin oil. Its principal use is to seperate the chyle from the chyme, with which it mixes in the duodenum.

To the above might be added *pituita*, phlegm; *saliva*, spittle; *mucus*; *lachrymæ*, tears; *sudor*, perspirations; all excretions from the blood, and in a healthy state, passing off from the body at particular periods; of these more may be found under their respective heads.

Of these component parts in different proportions are formed the three principal divisions of the body before mentioned, namely, the head, the trunk, and the extremities.

The *head* consists of *caput*, the head properly so called, and *cervix*, the neck. The parts of the head are external or internal.

External parts of the head.—The external parts of the head are, the hairy scalp and the face. The hairy scalp is composed of the common integuments; its uppermost part is called the *vertex seu fontinella*, the crown; the fourth part, the *sinciput;* the hind part, *occiput*, or back of the head; and the lateral parts, *tempora*, the temples. The face comprehends *frons*, the forehead; *oculus*, the eye; *auris*, the ear; *nasus*, the nose; and *os*, the mouth.

The *eye* is composed, externally, of *supercilia*, the eye-brows; *cilia*, the eye-lashes; *palpebræ*, the eyelids, the angles of which are called *canthe*, the margin *tarsus; glandulæ lachrymales*, the lachrymal glands; *puncta, lachrymalia; canales lachrymalis*, lachrymal ducts; *saccus lachrymalis*, the lachrymal sac; *ductus nasalis*, the nasal duct; *membrana conjunctiva seu albuginea*, the white.

The *internal* parts of the eye compose what is called the ball or globe. These are *tunicæ*, the coats; *cameræ*, the chambers; and *humores*, the humours; besides the muscles, fat, nerves, and glands. The principal coats of the eye are *tunica sclerotica*, or the *cornea*, which is the external and thickest coat; *tunica choroidea*, or the choroides, which is the middle. The perforated septum of the choroides has the name of *uvea;* the anterior lamina of the septum is termed the *iris;* the radiated plicæ of the posterior lamina *processus ciliares;* and the hole near the centre of the septum *pupilla*, the pupil, which is capable of contraction or dilation. The third and innermost of the coats is the *retina*.—*Camaræ*, the chambers of the eye, are the *camera, anterior*, and *posterior*, situated between the *cornea lucida*, or the anterior portion of the sclerotica and the uvea.—*Humores*, the humours of the eye, are three, namely, the *aqueous humour*, which is contained in the two chambers; crystalline lens or humour; and the *vitreous humour:* these two are enclosed in capsular tunicæ, called *crystallina* and *vitrea*. All these soft parts are enclosed in a funnel-shaped cavity, called an orbit, which is formed by seven bones, namely, the *os frontis, os sphenoidale, os othmoides, os maxillare, os malæ, os unguis*, and *os palati*. (See EYE.)

The *ear* is divided into the external and internal.

Auricula, the *external ear*, consists of a large cartilage that is divided into two portions, namely, the *pinna*, which is large and solid; and the *lobas* or lobe, which is soft and small, and forms the lower part. The external ear contains, besides several eminences, namely, the *helix, anthelex, tragus*, and *antitragus*; and also some depressions, as the *fossa auricularis*, or *scapha*, the *concha*, and the *meatus*.

The *internal ear* consists of *meatus auditorius internus*, the internal auditory passage; *membrana tympani*, the membrane which separates the external from the internal parts of the ear; and the labyrinth, which consists of three portions, namely, *cochlea*, the anterior; *vestibulum*, the middle; and the semicircular canals. (See EAR.)

The *nose* consists, *externally* of the root; the arch; back or spine, called the *spina nasi;* the sides of the arch; the tip of the nose; the *alæ* or *pinnæ*, which are the sides of the nostrils; the *nares*, or external nostrils.

The *internal parts of the nose* are, the internal nares, which consists of the *septum narium;* the *subseptum*, or pillar of fat under the *septum narium;* the convolutions; the *conchæ superiores;* the *sinus maxillares*, and *sinus sphenoidales;* the *ductus lachrymalis;* the *ductus patatius*, and the *membrana pituitaria*, which lines the whole cavity of the nostrils. (See NOSE.)

The *mouth* consists *externally*, of *labia*, the lips, which are upper and lower, and composed of a border or edge, and of commissures or angles; *fossula*, the depression which runs from the *septum narium* to the edge of the upper lip; *cheeks*, the upper prominent part of which is called the *mala; chin*, the anterior protuberance by which the lower part of the face is terminated.

The *internal parts of the mouth* are *palatum*, the palate, or roof of the mouth; *septum palati*, or *velum*

palati, the soft part of the palate, which forms two arches; *ærula*, the conical fleshy substance at the root of the tongue; *amygdalæ* or *tonsillæ*, the tonsils, two glandular substances, one on each side the basis of the tongue; *gingivæ*, the gums which contain the teeth; *maxillæ*, the *jaws*, which are composed of bones, and are either upper or lower; the *fræna*, of the lips; *lingua*, the tongue which consists of an apex, a root or basis, and a frænum. (See MOUTH.)

The internal parts of the head must next be examined: they are contained within an oval cavity, called the *cranium* or *skull*, which is formed of eight bones. (See BONES.) The contents of the skull are comprehended under the general name of *cerebrum*, the brain, which is immediately surrounded by two membranes, which are called *matres*, i. e. the *pia mater*, and the *dura mater*, between which lies a third membrane, called the *tunicai arachnoidea*. The duplicatures or circumvotions of these membranes are called *septa*, the upper of which has the name of the *falx*. The cerebrum consists of three portions, viz. the *cerebrum*, or brain, properly so called; the *cerebellum*, or little brain; and the *medulla oblongata;* to which is added sometimes a fourth, namely, the *medulla spinalis*, which fills the great canal of the *spina dorsi*.

The *cerebrum* is divided into two lateral portions called *hemispheres*, the extremities of which are termed *lobes*. Its substance is of two kinds, namely the outer, that is cortical, and is called the *cortex*; and the inner, which is called the *substantia medullaris*, or *substantia alba*.

The cavities of the brain, called *ventricles*, are four in number, and separated by a membrane called the *septum lucidum*. In each of these is the *choroid plexus*, formed of blood vessels. There is also another small cavity or *fossula*, called the *infundibulum*, the superior opening of which is called the *foramen commune anterius*. The principal prominences are the *corpus callosum*, the lower side of which forms a sort of vault called the *fornix;* the *corpora striata*, two striated prominences; *thalami nervorum opticorum; corpora quadragemina*, four medullary projections originally called *nates* and *testes;* the *pineal gland*, a cerebune tubercle on the nates, and the *crura cerebri*, two medullary columns proceeding from the basis of the brain to the medulla oblongata. To these may be added the *glandula pituitaria*, a small spongy body in the selta sphenoidalis.

On the *cerebellum* are observed four eminences, called *appendices vermiformes;* a fourth verticle; a valve, called the *valvula magna cerebri;* lamina, or ramifications, called *arbor vitæ*, the trunks of which are termed *pedunculi cerebelli*.

The *medulla oblongata* is a medullary continuation of the cerebrum and cerebellum, having anterior branches called *brachia*, and posterior, called *crura medullæ*. Its transverse is called *processus annularis*. The extremity of the medulla is called the *cauda;* its tubercles, *corpora olivaria et pyramidalia;* to which may be added the *medullary papillæ*, that are productions of the *infundibulum*.

The lower parts of the *medulla spinalis* is called *caudina equina;* and, in other particulars, it resembles the parts before described. From the cerebrum, and the other parts of the brain, arise the nerves which are dispersed through the body, (See NERVES.)

The *neck* may be added either to the head or the thorax, or to both. The fore part is called the throat, and the hind part the nape. The parts of the throat are the *fauces*, a cavity behind the tongue; *larynx*, which consists of five cartilages, a part of the *trachea; pharynx*, a muscular bag which receives the masticated food; *æsophagus*, or *gula;* the throat, a membraneous and muscular tube.

The salival glands, which are three pair, namely the *glandulæ parotides*, *maxillares*, and *sublinguales*, so called from their situation. (See NECK.)

The *trunk* consists of *spina*, the spine; *thorax*, the chest; and *abdomen*, the belly.

The *spine* is a bony column, consisting of a chain of *bones*, called *vertebra*, which are divided into true or false. (See VERTEBRÆ, BONES.)

The fore part of the thorax is the breast, the hind part the back; the lateral part the sides. These are severally formed by *sternum*, the breast-bone; *vertebræ dorsi*, the dorsal vertebræ; and *costæ*, the ribs. (See BONES, &c.) The thorax has externally the *mammæ*, or breasts, in the middle of which is the *papilla*, or nipple, surrounded by a disc called the *areola;* within are the *tubuli lactiferi*, or lactiferous ducts. The cavity of the thorax contains the *pleura*, a membrane with which it is lined; *mediastinum*, a membraneous septum; *pulmones*, the lungs; *cor*, the heart, and *pericardium*, the heart purse, a membraneous bag within which it is inclosed. The largest part of the heart is called the base, the narrower extremity the apex. It is divided by a membrane called the *septum medium*, or *septum cordis*, into two cavities, called *ventriculi*, ventricles, having several eminences or inequalities, called *fossulæ*, *thymus gland*, *ductus thoracicus*, and the *ductus lacteus*. (See THORAX.)

The *abdomen* is divided into four regions, three of which are anterior, and one posterior.—The *anterior regions* are the *epigastrii*, or upper region, which is divided into the *epigastrium*, or middle, and the *hypochondria*, or lateral parts; the *umbilical*, or middle region, consisting of the *regio umbilicalis*, or navel, in the middle, and the *ilia* or flanks, on the sides; the *hypogastrii*, or lower region, which is divided into the *pubis*, or middle part, and the *inguina*, or groins, on each side. The posterior region is the *regio lumbaris*, or loins.

The cavity of the abdomen is separated from that of the thorax by the muscular diaphragm, called the midruff. Its *viscera*, or contents, are inclosed in a membrane called the *peritonæum*, and are as follow, namely, the *ventriculus*, the stomach, which has two orifices, namely, the *cardia*, which is the upper, and the *pylorus*, which is the lower. It is composed of three coats, namely, the outermost, which is *membraneous;* the middle, which is *muscular;* and the inner, which is *nervous*, and covered with vessels. To these has been added a fourth, called *villous*. The stomach performs the office of *digestion*, which is now generally supposed to be effected by the *saccus gastricus*, or gastric juice, which flows from the *tunica nervosa*, aided by the continual contraction and relaxation of the muscular tunic, which is called the *peristaltic motion*. The *intestines* are a long pipe or canal, which by its convolutions forms six portions, three small and three large, namely, the *duodenum*, *jejunum*, *ileum*, *cæcum*, *colon*, and *rectum*. The small intestines have valves or folds, called *valvulæ conniventes;* the large intestines have fatty appendages, called *appendiculæ epiploicæ*. The membranes belonging to the intestines

London. Published by William Orr: Pater... Row, Nov. 29. 1832

are the *mesentery*, *mesocolon*, and the *omentum*, or *epiploon*, by which they are kept in their places and preserved from injuries, whilst by their peristaltic motion they expel the fæces collected in them. *Hepar*, the liver, is divided into two lobes, and is suspended in the body by means of ligaments, which connect it with the diaphragm, &c. It is composed of small vessels, or the ramifications of vessels, called *folliculi*, or *pori biliarii*, because in them is secreted the humour called the bile. The ducts of the liver are the *ductus hepaticus*; the *ductus cysticus*; and the *ductus echlodochus*, which is composed of the two former. On the hollow side of the liver lies the *vesicular fellis*, or the gall bladder.—*Pancreas*, a glandular *viscus*, consists of innumerable small glands that form one duct, called *ductus pancreaticus*, the pancreatic duct; its office is to secrete a juice distinguished by the name of the *succus pancreaticus*, the pancreatic juice.—*Lien* the spleen, is connected with the stomach by its blood-vessels called *vasa brevia*.—*Renes*, the kidneys, are composed of three substances, namely, the external, which is cortical, the middle, which is tubular; and the inner substance, which is medullary. They have also a peculiar membrane called the *membrana propria*, and an excretory duct called the *ureter*, the origin of which, expanded into the form of a funnel, is called the *pelvis*.—*Urinaria vesica*, the urinary bladder, a fleshy membraneous pouch, is divided into the body, the fundus, or upper part, and the neck which is the lower part, that is, contracted by the sphineter muscle.

The lower part of the abdomen is, in the skeleton, called the pelvis, which is formed by the *ossa ilia* and *ischia*, the *os sacrum*, the *os coccygis*, and the *ossa pubis*, and is terminated anteriorly by the *pudenda*, and posteriorly by the *clunes*, or buttocks. (See Bones.) The space between the *anus* and *pudenda* is called the *perinæum*.

The *pudenda*, or organs of generation, are distinguished into the male and female. The male organs are the *testes*, *vesiculæ*, *seminales*, *prostatæ*, and *penis*. —The *testes* are composed of many minute vessels, convoluted into different heaps, by means of which is formed a body called the *epididymis*. They are enclosed in three integuments or coats, namely, the *scrotum*, common to both, the *tunica vaginales*, and the *tunica albuginea*; besides a muscular lining of the *scrotum*, called the *dartos*, by which it is corrugated. The principal vessels are the *vasa præparantia*, commonly called the spermatic chord, and the *vasa deferentia*. The most important muscle is the *cremaster*. *Vesiculæ seminalis* are two in number, on each side of the bladder, which serves as recepticles for the seed. —*Prostatæ*, or *corpus glandulosum*, a conglomerate gland, situated at the neck of the bladder.—The *penis* is composed of two spongy substances, called *corpora cavernosa*, and covered with a particular integument, called the præputium. The extremity of the penis is the glans, or *balanus*, and the ligament by which it is tied to the glans is the *frænum*. The canal or urinary passage of the penis is the *urethra*, in which is a longitudinal orifice, called the *meatus urinarius*.

The female organs of generation are external or internal. The external are the *vulva*, *mons veneris*, *labia nymphæ*, and *clytoris*, the branches of which are called the *crura*.—The internal parts are called the *vagina*, or neck of the womb, the *hymen*, and the *carunculæ myrtiformes*, formed from the hymen and the *uterus* or womb.

The *uterus* is divided into three parts, namely, the *fundus* or upper part; the body, and the *cervix* or lower part, the entrance into which is called the *os uteri*. It is tied by two sorts of ligaments, called *ligamenta lata*, and *ligamenta rotunda*, i.e. two broad, and two round. To one end of the *ligamenta lata* are tied the *ovaria* or *testes* in females; along the other end run the *tubæ fallopianæ*. The vessels of the *uterus* are subject to a periodical discharge, which is called *menstruation*, and that which is discharged, the *menses*. The formation of the parts of an animal in the womb constitutes a *gravid uterus*. The commencement of this process is called *conception* or *impregnation*; and that which follows is *gestation* till the time of delivery, when the young is brought forth. The first rudiments of the animal are called the embryo, which, with the *umbilical chord* and *membranes* constitute the *ovum*. When the parts of the embryo are to be distinguished from one another, it is termed the fœtus. The membranes of the *ovum* and fœtus are the *amnios*, which is true or false, and the *chorion*. These membranes contain a fluid, called the *liquor amnii*, in which the embryo floats; and from the flacculent vessels of the amnion is formed the vascular substance called the *placenta*. The placenta and membranes which come away after the birth of the child are known by the name of *secundines*, or after-birth.

The *extremities* are superior and inferior. The superior extremities consist of *summitas humeri*, the shoulder; *brachium*, the arm; and *manus*, the hand. —The shoulder is composed of *clavicula*, the collar bone; *scapula*, the shoulder blade; and *axilla*, the armpit.—The arm is composed of the *os humeri*, *ulna*, and *radius*, the two last of which make what is called the fore-arm, in which anteriorly is the bend of the arm, and posteriorly, *angulus cubiti*, the elbow. The hand consists of the *carpus*, or the wrist; *metacarpus* and *digiti manus*, or fingers; *dorsum manus*, the back of the hand; and *vola* the palm.

The inferior extremities consist of *coxa* or *regio ischiadica*, the hip; *femar*, the thigh; *tibia*, the leg; and *pes*, the foot.—The thigh is composed of the *os femoris*, the thigh bone.—The leg is composed of the *genu*, the knee; *tibia*, *fibula*, *patella*, the knee-pan; *poples*, the ham; *cavum poplitis*, the hollow of the thigh; *sura*, the calf; and *malleolus*, the ancle.—The foot consists of *tarsus*, the instep; *mitatarsus*, or *dorsum*, the back; *digiti pedis*, the toes; and *planta*, the sole.

Having thus given a general outline of the various parts of the human structure, we may now proceed to a more detailed view of the osseous frame-work from which it derives its form and stability.

Plate 1, Anatomy, *fig.* 1, represents a front view of the male skeleton.

Head and neck.—*a*, the frontal bone; *b*, the parietal bone; *c*, the temporal bone; *d*, a portion of the sphenoid bone; *e*, the nasal bone; *f*, the malar, or cheek bones; *g*, the superior maxillary, or upper jaw bone; *h*, the lower jaw; *i*, the bones of the neck.

Trunk.—*a*, the twelve bones of the back; *b*, the five bones of the loins; *c*, *d*, the breast bone composed of two pieces; *e*, *f*, the seven true ribs; *g*, *g*, the five false ribs; *h*, the rump bone, or sacrum; *i*, the hip bones.

Upper extremity.—*a*, the collar bone; *b*, the shoulder blade; *c*, the upper arm bone; *d*, the radius; *e*, the ulna; *f*, the carpus, or wrist; *g*, the bones of the

hand; *h*, the first row of finger bones; *i*, the second row of finger bones; *k*, the third row of finger bones; *l*, the bones of the thumb.

Lower extremity.—*a*, the thigh bone; *b*, the knee-pan; *c*, the tibia, or large bone of the leg; *d*, the fibula, or small bone of the leg; *e*, the heel bone; *f*, the bones of the instep; *g*, the bones of the foot; *h*, the first row of toe bones; *i*, the second row of toe bones; *k*, the third row of toe bones.

Fig. 2, represents a back view of the male skeleton.

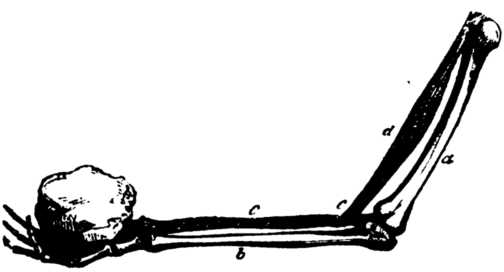
The head.—*a*, the parietal bone; *b*, the occipital bone; *c*, the temporal bone; *d*, the cheek bone; *e*, the lower jaw bone.

Neck and trunk.—*a*, the bones of the neck; *b*, the bones of the back; *c*, the bones of the loins; *d*, the hip bone; *e*, the sacrum.

Upper extremity.—*a*, the collar bone; *b*, the blade bone; *c*, the upper bone of the arm; *d*, the radius; *e*, the ulna; *f*, the bones of the wrist; *g*, the bones of the hand; *h*, the first row of finger bones; *i*, the second row of finger bones; *k*, the third row of finger bones; *l*, the bones of the thumb.

Lower extremity.—*a*, the thigh bone; *b*, the large bone of the leg; *c*, the small bone of the leg; *d*, the heel bone; *e*, the bones of the instep; *f*, the bones of the toes.

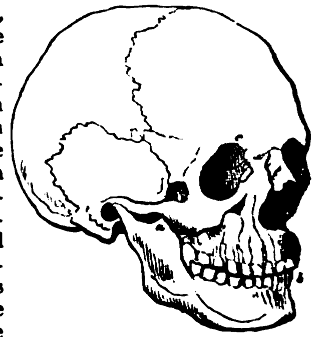
From this view of the human skeleton as a whole, we may proceed to an examination of the mechanical principles brought into operation in the various motions of the bones.



Both the lever and pulley perform prominent parts in animal mechanics. The arm furnishes us with a beautiful exemplification of the first of these simple mechanical instruments. In the above engraving our readers have a representation of the os humeri, *a*, nodius and ulna, *b*, *c*, with the connecting bones of the hand. Now, at first view, this arrangement appears but little fitted to answer any useful purpose, as the muscle or flexible cord *d*, which acts by its contraction from *e*, to elevate the weight in the hand, is placed nearer to the axis than the mass to be raised, and as such, strictly speaking, power is lost. But a closer examination shews that this mechanical disadvantage is more than compensated by the greater neatness and compactness of the limb. It lays nearer to the bone, and in addition to that circumstance there is less of contractible power required to move the extremity of the limb through a given space than if it acted directly at the point of the hand. The biceps and brachiæus exert a force equal to about twenty times that of the body raised.

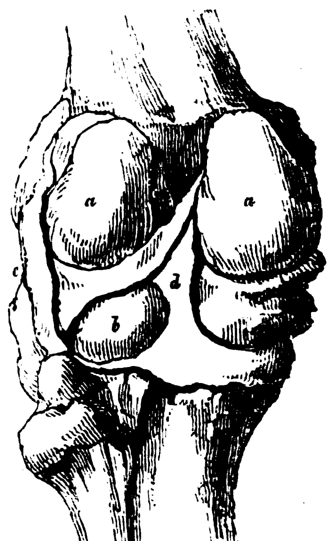
This force must not be confounded with the passive resistance of the bones, which frequently amounts to many hundred pounds, which a girdle passing round the lower extremities will readily support. In this way a man has been known to raise four butts of beer, and perform feats of strength which it would otherwise be difficult to understand.

Another, and very beautiful illustration, will be found in the head.



In the lower jaw, as shewn at *a b*, the the process goes on at a point much further removed from the centre of motion than the point where it is connected with the condyloid processes. On this account it is essential that a force much beyond that which is necessary for the mere crushing of the food should be exerted. In man it frequently amounts to three or four hundred pounds, and in the tiger, and some other of the inferior animals, to more than fifteen hundred pounds of effectual force,

While speaking of this portion of the human structure, we must not omit to notice two other mechanical powers, which are exhibited in the same figure. The teeth form very perfect illustrations of the use of the wedge, and a small perforation at *e* serves as a pulley to move the eye in its orbit.

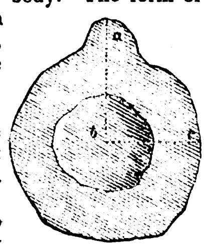


The way in which the axes or natural joints are lashed together, is represented in the accompanying engraving of the *tibia*; *a a* the apophyses are seen at the lower end of the os femoris covered with cartilage. The upper end of the *tibia* marked *b* and *d*, forms a ligament which moves a species of pulley or cartilage in the form of a half moon. A cross binding ligament which keeps the whole compact together is seen at *c*. Ligaments of a similar character are also represented at *e*. Now a more perfect axis or universal joint could hardly be conceived than the one thus described, and the ingenious mechanic cannot do better than go to nature for a guide in the general arrangement of the mechanical powers. A provision is also made for diminishing friction in the necessary motion of the ball and socket. A fluid constantly secreted serves precisely the same purpose as the reservoir arrangement in some of the new four-wheeled vehicles.

Another illustration of the wedge, as it occurs in conjunction with the theory of the arch, will not be out of place.

In the accompanying sketch the foot is seen supporting the lower end of the tibia, *a*. The os calcis, *b*, forms one point of support, whilst the toes being depressed by the muscular force form the other abutment. The series of bones from *a* to *c* form a system of wedges; and in addition to their great strength, act by their elasticity to break the momentum which the body of necessity acquires even in the falling or leaping from the smallest height.

Having thus illustrated some of the mechanical powers which are brought into operation in the human frame, we must briefly advert to the structure of the frame-work, or bones themselves. It was formerly believed that the bones consisted of fibres and lamella, but this view is now considered by the best anatomists as erroneous, and the view of Professor Scarpa of Pavia has been substituted. Considering it absurd to admit in one and the same bone two different structures, he has demonstrated by direct experiment, that the cellular, reticular, and vascular parenchyma constitute but the basis from which the other materials under apparently new forms are secreted, and that their intimate structure is in reality the same with that of the muscles, nerves, and several other parts of the body. The form of the bone best fitted for strength where elasticity is not required, is shown in the section. The marrow *b*, occupies the centre, and the bone formed in a circular layer, *a c*, has about three times the strength which it would possess if it assumed a solid form. The increased thickness exhibited at *a b*, serves to give the required strength in any peculiar direction. In closing this part of our subject we beg to direct the reader's attention to the articles *Muscles, Nerves, Brain*, &c.



ANCHOR. There are various species of metallic and wooden hooks, which under the general name of anchors are used for mooring of vessels. In the infancy of navigation, they appeared to have consisted of irregular masses of stone and bronze, which acted rather by the weight of the materials than the tenacity of the bed of the sea.

The anchors now generally made are so contrived as to support a great strain before they can be loosened or dislodged from their earth-bound bed. The parts of which an anchor is composed are the ring into which the cable is fastened, the beam or shank, which is the longest part of the anchor, the two arms, at the end of which are the two flooks or flukes, by some called the palms, which with their barbs fasten into the ground, and the flock, which is a long piece of wood fastened across the beam near the ring, and serving to guide the flukes in a direction perpendicular to the surface of the ground; so that one of them sinks into it by its own weight as soon as it falls, and is still preserved steadily in that position by the flock, which, together with the shank, lies flat on the bottom. In this situation it must necessarily sustain a great effort before it can be dragged through the earth horizontally. Should the anchor be displaced, it is said, in the sea phrase, "to come home."

The several parts of the anchor above enumerated bear the following proportions:—The length of the arm, from the inside of the throat to the bill, is the distance marked on the shank for the trend, taken from the inside of the throat; and three times that is the length of the shank from the tip of the crown; and the shank, from the tip of the crown to the centre of the ring, is the length of the iron stock; when made, the two arms, from the inside of the throat to the extremity of the bill, should form an arc of a circle containing 120 degrees.

The labour of raising the anchor when a chain-cable is employed, has been considerably diminished by a patent apparatus lately manufactured by Mr. Bailey of Holborn. It consists in the use of a small lever, which seizing on each link of the chain in succession, tends effectually to prevent its return, and enables a smaller number of men to effect the elevation than by the ordinary process.

ANCHYLOSIS; a stiffness or immobility of the joints. The existence of the disease is obvious to the eye. It is often connected with deformities of the limbs, and, in the anchylosis of the little bones of the ear, with deafness; in that of the joint of the lower jaw, with inability of chewing. Anchylosis may occasion the decaying of a limb, bleedings, aneurisms, &c., and may even become fatal. In the beginning of these diseases, the patient usually suffers pain in the limbs, a more or less audible rustling in moving the joint affected, a feeling of weakness and inability of directing the limb as it could be done in a state of health. An anchylosis usually arises from several causes, and afflicts sometimes the whole body, at other times one limb only. The anchylosis is sometimes constitutional; old people are more subject to it than young, and the male sex than the female. The real anchylosis is incurable. Excessive indulgence in animal passion may contribute to this disease; but it is, for the most part, the result of inflammation in the membrane lining the joints.

ANDANTE, in *Music*, denotes a time somewhat slow, and a performance distinct and exact, gentle and soothing. Andantino stands between andante and allegretto, at least according to the common notion; some assert that andantino implies a little slower motion than andante. The andante requires a delicate performance.

ANDROIDES, in *Mechanics*, an automaton in the form of a man. Vaucansons' *flute-player* may be considered as the most curious mechanical figure of which any correct account has been preserved. There is an interesting paper in the *Memoirs of the French Academy*, furnished by the artist himself, and he thus describes the apparatus:—The figure was about five feet six inches high, and was placed upon an elevated square pedestal. The air entered the body by three separate pipes, into which it was conveyed by nine pairs of bellows, which expanded and contracted in regular succession by means of an axis of steel turned by the machine. The three tubes which conveyed the air from the bellows, after passing through the lower extremities of the figure, united at the chest; and ascending from thence to the mouth, passed through two artificial lips. Within the cavity of the mouth was a small moveable tongue, which

by its motion at proper intervals admitted or intercepted the air in its passage to the flute. The fingers, lips, and tongue derived their specific movements from a steel cylinder turned by clock-work. The cylinder was divided into fifteen equal parts, which by means of pegs pressing upon a like number of levers, caused the other extremities to ascend. Seven of these levers directed the fingers, having rods and chains fixed to their ascending extremities; which being attached to the fingers, made them to ascend in proportion as the other extremity was pressed down by the motion of the cylinders, and vice versa. Three of the levers served to regulate the ingress of the air, being so contrived as to open and shut by means of valves the communication between the lips and reservoir, so that more or less strength might be given, and a higher or lower note produced as occasion required.

The lips were directed by four similar levers; one of which opened them to give the air a freer passage; another contracted them; a third drew them backward, and the fourth pushed them forward. The remaining lever was employed in the direction of the tongue, which by its motion shut or opened the mouth of the flute. The varied and successive motions performed by this ingenious androides were regulated by a contrivance no less simple than efficacious. The axis of the steel cylinder or barrel was terminated by an endless screw composed of twelve threads, above which was placed a small arm of copper with a steel stud made to fit the threads of the worm, which by its vertical motion was continually pushed forward. Hence, if a lever was moved by a peg placed on the cylinder, in any one revolution, it could not be moved by the same peg in the succeeding revolution in consequence of the lateral motion communicated by the worm. By this means the size of the barrel was considerably reduced; and the statue not only poured forth a varied selection of instrumental harmony, but exhibited all the evolutions of the most graceful performer.

Anemometer. An instrument for measuring the force and velocity of the wind. For this purpose a variety of contrivances have been suggested, many of which display no inconsiderable share of ingenuity. It has been proposed to suspend a rod, in the manner of a pendulum, with a flat board instead of a ball at its lower extremity. It is obvious, that when the wind impinges upon such a board, it will, according to its strength, force it more or less out of a vertical position, and therefore the angle of deviation will be the measure of that strength. Another contrivance resembles a small windmill, by the number of the revolutions of which, in a given time, the result desired may be obtained. Instruments have even been described, which express upon paper, not only the several winds that have blown during the space of twenty-four hours, but at what hour they began and ended, with the strength and velocity of each; but they are much too complicated for general use.

Anemoscope. Every contrivance which indicates the direction of the wind. The vane upon towers and roofs is the simplest of all anemoscopes. There are also some, where the vane turns a moveable spindle, which descends through the roof to the chamber where the observation is to be made. On the ceiling of this apartment a compass-card is fixed, and, whilst the wind turns the vane together with the spindle, an index fixed below points out the direction of the wind on the card. Some are so made as, even in the absence of the observer, to note down the changes of the wind. Among the most perfect of this kind, is that of Professor Moscati, and of the Cavalier Marsilio Landriani.

Aneurism. The swelling of an artery, or the dilatation and expansion of some part of an artery. This is the true aneurism. There is also a spurious kind of aneurism, when the rupture or puncture of an artery is followed by an extravasation of blood in the cellular membrane. If the external membrane of the artery is injured, and the internal membrane protrudes through, and forms a sac, it is called *mixed aneurism*. Lastly, there is the varicose aneurism, the tumour of the artery, when, in bleeding, the vein has been entirely cut through, and at the same time the upper side of an artery beneath has been perforated, so that its blood is pressed into the vein. The genuine aneurisms arise partly from the too violent motion of the blood, partly from a preternatural debility of the membranes of the artery, which is sometimes constitutional. They are, therefore, more frequent in the great branches of the arteries; in particular, in the vicinity of the heart, in the arch of the aorta, and in the extremities, for instance, in the ham and at the ribs, where the arteries are exposed to frequent injuries by stretching, violent bodily exertions, thrusts, falls, and contusions. They may, however, be occasioned also, especially the internal ones, by diseases, violent ebullitions of the blood, by the use of ardent spirits, by vehement passions and emotions, particularly by anger: in such cases the arteries may be ruptured, and sudden death produced. The external aneurisms are either healed by continued pressure on the swelling, or by an operation, in which the artery is laid bare, and tied above the swelling, so as to prevent the flow of the blood into the sac of the aneurism, which contracts by degrees. Sometimes the ligature is applied both above and below the aneurism.

Angle. See Geometry.

Animal Heat is that property of all animals by means of which they preserve a certain temperature, which is quite independent of that of the medium by which they are surrounded, and appears rather to be in proportion to the degree of sensibility and irritability possessed by them. It is greatest in birds. The more free and independent the animal is, the more uniform is its temperature. On this account, the human species preserves a temperature nearly equal, about 96—100° Fah., in the frozen regions at the pole, and beneath the equator; and on this account, too, the heat of the human body remains the same when exposed to the most extreme degrees of temperature; in fact, cold at first rather elevates, and extreme heat rather depresses the temperature of the human body. Fordyce and Blagden endured the temperature of an oven heated almost to redness, and two girls in France entered a baker's oven heated to 269° Fah., in which fruits were soon dried up, and water boiled. A Spaniard, Francisco Martinez by name exhibited himself, a short time since at Paris, in a stove heated to 279° of Fah., and threw himself, immediately after, into cold water. Blagden was exposed in an oven to a heat of 257°, in which water boiled, though covered with oil. There is also a remarkable instance of a similar endurance of heat by the *convulsionnaires*, as they were called, upon the grave of St. Medardus, in France. A certificate signed by

several eye-witnesses, among whom were Armand, Arouet, the brother of Voltaire, and a Protestant nobleman from Perth, states that a woman named la Sonet, surnamed the *salamander*, lay upon a fire nine minutes at a time, which was repeated four times within two hours, making in all, thirty-six minutes, during which time fifteen sticks of wood were consumed. The correctness of the fact stated is allowed even by those opposed to the abuses in which it originated. The flames sometimes united over the woman, who seemed to sleep; and the whole miracle is to be attributed to the insensibility of the skin and nerves, occasioned by a fit of religious insanity. These facts are the results of a law of all living substances, viz. that the temperature of the living body cannot be raised above certain limits, which nature has fixed. There is also an increased flow of perspiration, by means of which the heat of the body is carried off. The extreme degrees of cold which are constantly endured by the human frame without injury are well known, and are to be explained only by this power in the living body to generate and preserve its own heat. The greater the irritability of individuals, whether from age, sex, or peculiarity of constitution, the greater the warmth of the body: it seems also to depend, in part, upon the quickness of the circulation of the blood: thus children and small animals, whose circulation is lively, feel the cold least. The heat and the power of preserving it differ also in the different parts of the body; those appearing to be warmest in which there is the most copious supply of blood, as the brain, the head and neck, the lungs and central parts of the body. We see also, that when the irritability of the body, or of any part of it, is particularly increased, the heat of the part undergoes a similar change. Increased activity and motion of the body, as in walking, running, &c., and diseases of increased excitement, as fever and inflammation, produce a similar increase in the temperature of the body. All this justifies the conclusion, that animal heat depends chiefly upon the irritability of the body, and is thus most intimately connected with the state of the nervous system. This view is confirmed by the late experiments of Brodie, who ascribed this power of the living body to the influence of the brain. He destroyed the brain of a rabbit, and kept up the respiration by artificial means; but the heat of the animal regularly diminished.

Animal Life. Life, in the earlier periods of scientific knowledge, was attributed only to animals. With the progress of science, however, it was extended to plants; and man, who had been hitherto regarded as a distinct order of being, was now considered as but a higher animal, intimately connected with the whole chain of the organized world. The great discoveries in chemistry, magnetism, electricity, and galvanism, have shown that those elements and principles, on which rest the laws of life, pervade nature in the most various forms and combinations; that there is no harsh and abrupt distinction between the animate world and the inanimate, but, on the contrary, an intimate connexion between the energy which makes the crystallizing mineral follow the law of the strictest regularity, or the stone fall from the height, and that which makes the heart of man beat. The difficulty of defining animal life has, therefore, been greatly increased. What is animal life? What constitutes an animal? Since mankind began to cultivate philosophy, they have sought in vain for a definition of life. It would require much more metaphysical discussion, to enter at all satisfactorily into this subject, than the character of the present work allows: and we are constrained to offer the reader only the following remarks on this most interesting subject.—Linnæus defines an animal an organized, living, and sentient being. An animal is indeed organized; but are not vegetables organized also? Animals are endowed with sensation; but are all, without exception? and do not some plants possess this faculty? Locomotion is not a more certain characteristic of animals than life or irritability, for many animals are destitute of this power, and vegetate like plants, the images of torpidity and insensibility. Neither are the chemical characters of animal substances more distinct; animals are chiefly composed of azote, and vegetables of carbon; but, among the latter, some are, like the former, composed principally of azote. In whatever point of view we consider these two kingdoms of nature, we find them blended in so many ways, and separated from each other by such imperceptible gradations, that it is impossible to draw a line, at which we can affirm that animal life ends, and the vegetable begins.

Animal Magnetism. See Magnetism.

Animal Matter is the protection, the residence, and the visible form of animal life. The simple elementary substances are combined by the powers of life, according to the objects for which it was destined, into various animal substances, falling naturally under certain divisions, which all, however, in some respects, comprehend each other. They may be enumerated under two heads, fluids and solids. The first of these have no distinct form or organization, and yet possess properties, by means of which, when acted upon by the vital powers, they are capable of forming all the various organs of the body; and it is surely a most unnatural view of them to regard them as destitute of life. In the following list of animal fluids, which, in the processes of life, pass constantly the one into the other, we find all the fluid parts or kinds of animal matter: they are chyme, chyle, lymph, venous and arterial blood, and the various secreted and excreted fluids. The second division comprehends all the solid parts of the animal frame, both hard and soft, and are of nearly the same essential structure in all animals, although variously arranged, according to their species. A minute description of all these belongs to anatomy; we shall merely enumerate them. They appear in the form of; 1, bones, constituting the basis, the frame of the animal, and found in all animals till we come to shell-fish (whose shells may be even regarded as external bones), and to still inferior animals, possessing no substitute for bones; 2, ligaments and fibrous membranes, connecting and covering them; 3, muscles which move them, and place the body and its limbs at the command of the animal; 4, fat and marrow, which soften and lubricate all the various parts of the body; 5, nervous or medullary matter constituting the brain and nerves, in which the vital power seems more particularly to reside; 6, the cellular substance, or membrane, which pervades all parts of the frame, and serves to connect them, and to furnish with the fat, which fills its cells, a soft bed for the vessels, nerves, &c.; 7, the mucous membranes, lining the whole body, from the nose and mouth to the parts at which all evacuations take place, and thus coating the mouth, throat, lungs, stomach, and bowels, in which the important func-

tions of digestion and respiration are performed; 8, the serous membranes, which line all the large cavities, and which, by the soft fluid that always moistens their surface, render easy the motion of all the internal organs upon each other; 9, the vascular system, or vessels of all descriptions, conveying the blood to all the organs of the body, and returning it from them to the heart and lungs,; and 10, the glandular system, by means of which various fluids important to life are separated from the blood, or rather formed from it by a new composition of its original elements. "These several classes of animal matter comprehend all the various forms in which it appears in all animals of all kinds; the heart of a frog and of a philosopher being composed of similar muscular fibres, and their brains of similar nervous matter." These obvious component parts of animals are, however, separable by the art of the chemist into more simple and ultimate elements. The following are all that are at present known to exist, and of these some are peculiar to animals, while others enter, more or less, into the composition of all parts of the creation. They are, 1, iron, which is found chiefly in the blood, in the state of an oxide; 2, lime, which enters largely into the composition of bones, shells, &c.; 3, silex, in the enamel of the teeth; 4, water, which gives their liquid character to all the animal fluids; 5, air which is found, mixed with watery vapour, in all the cavities of the body; 6, soda, united with various acids, in all the various fluids of the body; 7, ammonia, in the perspiration, urine, &c.; 8, sulphur; 9, phosphorus, in the bones, &c.; 10, carbon; 11, various acids, as the phosphoric, muriatic, uric, lactic, formic, &c., which are found, variously combined, in most of the solid and fluid parts of the body; 12, gelatin, or glue; 13, albumen, constituting the chief part of the transparent and colourless membranes, and the fluids which moisten them; 14, fibrin, constituting the basis of all the muscles, ligaments, &c., and the most important ingredient in the composition of the blood. Most of these substances are again susceptible of still farther analysis, by which they may be resolved into the simple gases, as nitrogen, hydrogen, oxygen, &c.; so that it appears that the ultimate elements of all parts of the visible world are nearly the same in their essential character.

ANKER, a liquid measure of about thirty gallons,

ANNEALING, or NEALING, as it is called by the workmen, is a process particularly employed in the glass-houses, and consists in putting the glass vessels, as soon as they are formed, and while they are yet hot, into a furnace or oven, not so hot as to remelt them, in which they are suffered to cool gradually. This is found to prevent their breaking so easily as they otherwise would, particularly on exposure to heat. Unannealed glass, when broken, often flies into powder, with great violence, and in general it is in more danger of breaking from a very slight stroke than from one of considerable force. An unannealed glass vessel will often resist the effect of a pistol-bullet dropped into it; yet a grain of sand, falling into it, will make it burst into small fragments, and, which is very curious, it will often not burst until several minutes after being struck. The same phenomena are still more strikingly seen in glass-drops or tears: they are globular at one end, and taper to a small tail at the other: they are the drops which fall from the melted mass of glass on the rods, on which the bottles are made, into the tubs of water which are used in the work. Those which remain entire, after having fallen into the water, show the properties of unannealed glass in the highest degree. They will bear a smart stroke on the thick end, but if the small tail is broken, they burst into powder, with a loud explosion. The reason of this singular fact is differently given. A similar process is used for rendering cast-iron vessels less brittle.

ANNUITIES are periodical payments of money, amounting to a certain annual sum, and continuing either a certain number of years, as 10, 20, or 100, or for an uncertain period, to be determined by a particular event, as the death of the annuitant, or that of the party liable to pay the annuity, or of some other person, or indefinitely; and these last are called *perpetual* annuites. The payments are made at the end of each year, or semi-annually, or at the end of every quarter, or at other periods, according to the agreement upon which the annuity arises; and where it is liable to cease upon the happening of an event, the time of the occurrence of which is uncertain, as the death of a person, and such event happens after the expiration of a part of the time between one payment and another, neither the annuitant nor his heirs will be entitled to any proportional part of a payment for such time, unless some express provision is made for this purpose in the contract. The probability of the loss of such fractional part is to be taken into consideration in estimating the present value of the annuity; if the life in question is, according to the tables of longevity, good for 5½ years, an annuity for such life is worth more than if it were good for only just 5 years, since the probability of its continuing 6 years is greater. As an annuity is usually raised by the present payment of a certain sum, as a consideration whereby the party making the payment, or, some other person named by him, becomes entitled to an annual, semi-annual, quarterly, or other periodical payment of a certain sum, for a stipulated number of years, or for a period to be determined by the happening of a certain event; the rules and principles by which this present value is to be computed have been the subjects of much scientific investigation. The present value of a perpetual annuity is evidently a sum of money that will yield an interest equal to the annuity, and payable at the same periods; and an annuity of this description, payable quarterly, will evidently be of greater value than one of the same amount payable annually, since the annuitant has the additional advantage of the interest on three of the quarterly payments, until the expiration of the year; or, in other words, it requires a greater present capital to be put at interest, to yield a given sum per annum payable quarterly, than to yield the same annual sum, payable at the end of each year. The present value of an annuity for a limited period, is a sum which, if put at interest, will at the end of that period give an amount equal to the sum of all the payments of the annuity and interest; and, accordingly, if it be proposed to invest a certain sum of money in the purchase of an annuity for a given number of years, the comparative value of the two may be precisely estimated, the rate of interest being given. But annuities for uncertain periods, and particularly life annuities, are more frequent, and the value of the annuity is computed according to the probable duration of the life by which it is limited. Many such annuities are granted for public services. But life annuities are often

created by contract, whereby the government or a private annuity office agrees, for a certain sum advanced by the purchaser, to pay a certain sum annually, in yearly, quarterly, or other periodical payments, to the person advancing the money or some other annuitants named by him, during the life of the annuitant; or the annuity is granted to the annuitant, his heirs and assigns, during the life of some other person, or during two or more joint lives, or during the life of the longest liver or survivor among a number of persons named in the act or agreement whereby the annuity is raised. Such annuities are usually made transferable, and are sold and purchased in the market as a species of public stocks. When granted by a government, they are generally one mode of raising loans; when created by a contract with a private corporation or company, their object usually is, to give the annuitant the use, during his life, not only of the income of his capital, but of the capital itself. If a person, having a certain capital, and intending to spend this capital and the income of it during his own life, and leave no part to his heirs, could know precisely how long he should live, he might lend this capital at a certain rate during his life, and by taking every year, besides the interest, a certain amount of the capital, he might secure the same annual amount for his support during his life, in such manner that he should have the same sum to spend every year, and consume precisely his whole capital during his life. But, since he does not know how long he is to live, he agrees with the government, or an annuity office, to take the risk of the duration of his life, and pay him a certain annuity during his life, in exchange for the capital which he proposes to invest in this way. The probable duration of his life, therefore, becomes a subject of computation; and, for the purpose of making this calculation, tables of longevity are made, by noting the proportions of deaths, at certain ages, in the same country or district. An annuity guaranteed by a pledge of real estate is worth more than one of the same amount resting upon the mere promise of a government or private company. Accordingly, for the purpose of raising money upon better terms, that is, of selling the annuity for a greater present value, some of the governments of Europe have occasionally pledged their domains or the income of certain taxes, to secure the payment of the annuities. For the theory of annuities see INTEREST.

ANODYNES; means for soothing pain. As the pain may arise from very different causes, the means for counteracting it must be very different. Thus, for instance, a pain may be produced by inflammation; and, in this case, cooling means, lukewarm poultices, sometimes even bleeding or purging, will be the proper anodynes. At other times they should be of an inflammatory kind; for instance, in debility of the nerves, cramps, or spasms. in the stricter sense, we understand by anodynes such remedies as lessen the susceptibility to painful impressions, by diminishing the sensibility of the nerves. In early times, when the doctrine of poisons and antidotes was more attended to than any other part of medicine, the soothing quality of many simples was also more closely observed, and a particular class was formed in this way. As this property existed in a high degree in opium, then already in use, it not only obtained the first place in this class of simples, but the name *anodyne* was given to all mixtures containing it. The use of anodynes is proper only when the cause of pain cannot be removed, or not so soon as its violence requires, or where the pain itself is more injurious than the cause which produces it; as when it prevents a favourable crisis, by rendering the patient unable to sleep.

ANTIMONY is a bluish-white, brittle metal, of a scaly or foliated texture; it has a brilliant lustre, but becomes tarnished by exposure to the air; its specific gravity is 6.7. In this state, it is called the *regulus of antimony*, and is used as an ingredient in the manufacture of the best pewter, in some type-metal, and in casting leaden medallions. By exposure to heat it melts, and becoming oxydized, rises in dense white fumes, formerly called *argentine flowers of antimony*. Antimony forms with oxygen several oxides, with which the acids unite and give rise to numerous salts, the most important of which is the triple one, called *tartrate of potash and antimony*. It is manufactured in the large way by mixing one pound of glass of antimony with a pound of super-tartrate of potash, and boiling the mixture in a gallon of water for an hour: it is then filtered, evaporated, and set by to crystallize. Tartar emetic is the most generally used antimonial medicine; and it may be so managed as to produce either sweating, purging, or vomiting. Antimony is found in its metallic state in minute quantities in several countries, and in occasional mixture with ores of silver, lead, and copper; but it is from its combination with sulphur, in which state it occurs abundantly in Auvergne, Scotland, and Hungary, that the antimony of commerce is furnished. This mineral, the sulphuret of antimony, is found in compact, foliated, and radiated masses, as well as in distinct rhombic prisms. Its colour is a light lead-grey; it is dull, and often iridescent. Specific gravity, 4.3. It melts in the flame of a candle, and before the blow-pipe, on charcoal, is wholly evaporated, with a sulphureous odour. It is composed of antimony 72.86, and sulphur, 27.14, and in its composition exactly resembles the artificial compound which possesses the same properties. To obtain the crude antimony of commerce, the above ore is reduced to fragments, and put into large earthen pots, with holes in their bottoms, and these are inserted into other similar vessels; heat is applied to the upper ones, which causes the sulphuret of antimony to separate from its stony case, and flow into the lower vessels, which are kept cold; here it concretes into fibrous, crystalline masses, without having undergone any change in its nature during the process. In this condition, it constitutes the crude antimony of commerce. From this substance the regulus of antimony is prepared, by roasting the sulphuret of antimony in a reverberatory furnace, until it forms a grey oxide, 100 weight of which is afterwards mixed with 8 or 10 pounds of argal, or crude tartar, and smelted in large melting pots in a wind-furnace. It also affords, by calcination and subsequent fusion in earthen crucibles, the glass of antimony, which is of so much importance in the preparation of tartar emetic. The Kermes mineral, a popular medicine, is likewise prepared from the sulphuret of antimony, by boiling crude antimony and pearl-ashes; the Kermes mineral is deposited in the form of a purplish-brown powder. The supernatant liquid, on the addition of any acid, yields an orange sediment, called *golden sulphur of antimony*,

which is used by the calico-printers as a yellow dye.

ANTISEPTICS; remedies against putrefaction. The ancients thought it possible, by certain preparations, to resist a general tendency to putrefaction, which they supposed to exist in the system. The moderns have only attempted to prevent the affection of the sound by the mortified parts, by means of external applications, which favour their separation. We are indebted to chemistry for most of these remedies, which generally operate by absorbing the liquids and gases of the gangrenous parts. Among antiseptical substances, charcoal-powder has hitherto been one of the most esteemed, but the chloride of lime has been recently discovered to be much more efficacious in arresting the progress of putrefaction. Placed in contact with the affected parts, it destroys the offensive odour which they exhale, and prevents the extension of the corruption. The practitioner must adapt the treatment to particular circumstances: to inflammation he opposes bleeding, emollients, &c.; to weakness, nourishing food, tonics, &c.; at the same time with the local application of the antiseptic. Under the head of antiseptics we must not omit to notice the Pyroligneous Acid, which see.

ANTISPASMODIC; a name given to any thing which has the power of relieving the cramp. Antispasmodics are more accurately defined, medicines proper for the cure of spasms and convulsions. Opium, balsam of Peru, and the essential oils of many vegetables, are the most useful of this class of medicines.

ANTISYPHILITIC; a term applied to remedies used in cases of syphilis. They are almost numberless; and there exists, perhaps, not one substance in the three kingdoms of nature to which an antisyphilitic power has not been ascribed. The most efficacious are preparations of mercury, which is administered in a great variety of ways; sudoriferous vegetables, the combinations of which are also extremely numerous; and preparations of gold, particularly of the muriate of this metal.

ANVIL, a smith's utensil, serving to place the work on to be hammered or forged. The face, or uppermost surface of the anvil, must be very flat and smooth, without flaws, and so hard that a file will not touch it. At one end there is sometimes a pike, bickern or beak-iron, for the rounding of hollow work. The whole is usually mounted on a firm wooden block. Forged anvils are better than those of cast work, and the best have the upper part made of steel. Locksmiths have a smaller kind of anvil called the *stake*, which is moveable, and placed ordinarily on their work-bench. Its use is for setting small cold work straight, or to cut or punch on with the cold chissel or cold punch.

AORTA; the great artery which rises immediately out of the left ventricle of the heart. It is divided into two grand trunks, distinguished by the epithets *ascending* and *descending*. (See ARTERY.)

APHELION, the term employed to mark that part of the orbit of the earth, or any other planet, in which it is at the point remotest from the sun. This also applies to a satellite; for the moon has her aphelion as well as the planets.

APOGEE; that point in the orbit of the sun, or of a planet, which is at the greatest distance possible from the earth, in contradistinction to the point of greatest nearness, which is called the *perigee*. The ancient astronomers, regarding the earth as the centre of the system, paid particular attention to these points, which the moderns, making the sun the centre, change for the *aphelion* and *perihelion*.

APEPSIA; indigestion. Abstemiousness and excess are alike causes of indigestion. An over distension of the stomach may in some measure injure its proper tone; and long fasting, by inducing a bad quality in the juices secerned into the stomach, renders it feeble, and generates wind. Hard drinking, and any of the causes of an anorexy, also injure digestion.

APERIENTS, in the *Materia Medica*, an appellation given to such medicines as facilitate the circulation of the humours by removing obstructions. The five aperient roots of the shops are, smallage, fennel, asparagus, parsley, and butchers' broom.

APOPLEXY is the name applied to a disease which occurs very suddenly, as if a blow had been inflicted upon the head, and deprives the person of consciousness and voluntary motion, while the respiration and action of the heart continue, although much oppressed. In a complete apoplexy, the person falls suddenly, is unable to move his limbs or to speak, gives no proof of seeing, hearing, or feeling, and the breathing is stertorous or snoring, like that of a person in deep sleep. In a case of less violence, the symptoms are more moderate. Consciousness sometimes remains in part; some power of motion is retained upon one side, or in some parts at least; the speech is not entirely lost, but is only an unintelligible muttering of incoherent words. The immediate cause of this disease is some affection or injury of the brain, or of some portion of it; and it is most commonly produced by a fulness of blood in the head, either remaining in the blood-vessels, or poured out in or upon the brain, from their rupture in some part, and in sufficient quantity to exert considerable pressure upon that organ. As the state of the whole body depends much upon the sound condition of the brain and nerves, it is evident that such an unnatural state of these organs cannot continue long without danger to life. The termination and effects of the disease vary with the violence of the attack; and it is either fatal in a few hours, or after a few days, during which a degree of fever is often observed, or the patient recovers, entirely or with a weakness or lameness of one or more limbs. The immediate cause of the symptoms first occurring, and of those remotely subsequent, is not known with absolute certainty; but from the examination of the bodies of those who have died with this disease, or in whom death has been produced by mechanical injuries to the head, which have been attended by similar appearances; and from the entire similarity of the symptoms in persons whose brains are injured by the pressure of bones, or blood, or in whom the brain exposed by some wound is purposely compressed, &c., to the symptoms presented by apoplexy; there is scarcely room to doubt that genuine, complete apoplexy is produced by the pressure of blood (whether extravasated or not) upon the brain. This arises from the destruction of the equilibrium or balance of the circulation by various causes, by which an unnatural quantity of blood is forced into an otherwise healthy brain, or the brain and its vessels so weakened, that they are unable to sustain the pressure of the usual quantity of blood. Some of these causes operate directly upon the brain, as strong passions, hard study, exhaustion from fatigue,

&c.; others, indirectly, through the medium of the stomach, as when this disease is produced by indigestible food, &c. The disposition to it is sometimes hereditary, and is most usually found to accompany a short, full person, a short neck, and a system disposed to a too copious sanguification. It sometimes also occurs in people who are exhausted by old age, excessive labour or anxiety, and in these cases the brain seems to be too weak to perform its common functions, and the efforts required of it produce an injurious or destructive flow of blood to it. It will be readily conjectured from what has been said, that the cure of this disease is by no means easy, as the treatment must be accommodated to the various causes which may have produced it. It is at all times a disease of great danger, but by no means always fatal; and those affected by it sometimes recover as entirely as from any other complaint, although some lameness or defect of motion is apt to remain, either in the limbs, the organs of speech, the eyes or mouth, or some other part. A fatal result is to be anticipated when the consciousness and feeling are entirely lost; when the eye is insensible to light, and the pupil does not contract; when the patient cannot swallow, the respiration grows more laborious, and froth or blood appears at the mouth or nose. But if, on the contrary, the remedies used appear to afford relief, and produce a gradual diminution of the symptoms above described, a favourable result may be expected. Although an attack of apoplexy comes on for the most part suddenly and unexpectedly, yet it is often preceded by appearances which give warning of its approach These are a high colour of the whole face, giddiness or vertigo, sparks or flashes of light before the eyes, noises in the ears, bleeding at the nose, and pain in the head. The danger in such cases may most commonly be averted by bleeding and abstemious diet, to be continued till these symptoms are removed. When a person is unfortunately attacked by apoplexy, the first step should be to open the cravat and collar, so as to leave the neck free: if it be a short time after a meal, or if the last meal has been of an indigestible character, the stomach should be emptied by an emetic, or by tickling the throat with the finger, without waiting for a physician, and at the same time a vein or two should be opened, so as to produce a free flow of blood, which should be continued, if the face is flushed and red, till relief is obtained. Subsequent treatment will of course be directed by a medical attendant. Great care should be taken in such cases that no attempt is made to arouse the person by rubbing or any sort of stimulation, internal or external, as these can only do harm. Paralysis, or palsy, is sometimes a consequence of apoplexy, but it is more commonly produced by causes of a different character, and constitutes a different disease. (See PALSY.)

APPOGGIATO denotes in music, and particularly in song, a blended and not abrupt utterance of the tones; so that they insensibly glide and melt into each other without any perceptible break. It is from *apoggiare*, to lean on. Hence, also,

APPOGGIATURA, a small additional note of embellishment preceding the note to which it is attached, and taking away from the principal note a portion of its time.

APPROXIMATION; a term used in mathematics to signify a continual approach to a quantity required, when no process is known for arriving at it exactly. Although by such an approximation the exact value of a quantity cannot be discovered, yet in practice it may be found sufficiently correct; thus the diagonal of a square, whose sides are represented by unity, is $\sqrt{2}$, the exact value of which quantity cannot be obtained; but its approximate value may be substituted in the nicest calculations. This process is the basis of many calculations in pure and applied mathematics, and is of frequent use and great importance in all practical operations.

APSIDES. The orbits of the planets and comets are ellipses, in one of the foci of which is the sun. In the same way the satellites move round their planets. The nearest point of the ellipse from that focus, is the lower *apsis*, and is also called, in the orbits of the planets and comets, *perihelion*; the farthest point or the higher apsis is called *aphelion*. In the orbit of our moon, the corresponding terms are *perigee* and *apogee*. The straight line which joins the apsides, or the transverse axis of the ellipse, is called the *line of the apsides*. It moves slowly forward in the direction of the planet's course. Therefore, if the earth sets out from the apogee, it must make more than a whole revolution in its orbit before it returns to the same point. The time which it employs in so doing is sometimes called an *anomalistical year*. It is therefore longer than a tropical one.

AQUA FORTIS; nitric acid in a diluted state. (See ACID.)

AQUA MARINA. (See BERYL.)

AQUA REGIA. The name given by the alchemists to what is now called *nitro-muriatic acid*,—a mixture of nitric and muriatic acid, yellow, and possessing the power of readily dissolving gold, which neither possessed separately. (See ACID.)

AQUARIUS, the Water-carrier, in *Astronomy*, the eleventh sign in the zodiac, reckoning from Aries; from which also the eleventh part of the zodiac takes its name. The sun moves through Aquarius in the month of January.

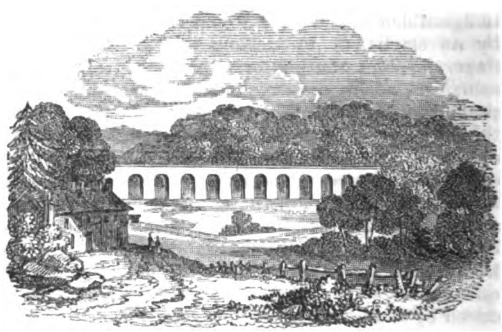
AQUA TINTA; the art of engraving on copper after the manner of Indian ink, by which happy imitations are made of figures that have been drawn with the pencil in Indian ink, bistre, sepia, &c., particularly those which are on a large scale. There are several sorts of it. In the first, after the outlines o the figure have been etched, finely powdered mastic (*colophonium*) is sifted over the plate, which is then warmed over coals, that the mastic may be melted. In this way insensible spaces are formed between the particles of mastic upon which the nitric acid is afterwards to act. The work then goes on as in the mezzo tinto, only that the scraper is used in this, and the pencil in that; and all the places where there is to be no work or shade are covered with a thick black varnish, on which the acid does not act. The nitric acid is now poured on, and left to stand as long as is necessary for the lightest shade—about five minutes. The light shades are now stopped out with varnish, and the acid allowed to act a second time, and this stopping out is continued till we come to the deepest shades, which are bit in last. This method is best for historical and architectural subjects; but in landscapes, in which the trees require more freedom of the pencil, the second is used. In this a good etching ground is spread over the plate, and covered by means of a hair-pencil, with oil of lavender or oil of turpentine, to which lamp-black is

sometimes added. The oil softens the ground, which may be wiped off with a fine linen cloth, leaving all the marks made with the pencil apparent on the copper. Then, as in the first process, fine mastic is sifted over the plate, melted in and etched. This operation may be repeated many times, according as there are more or fewer tints in the original. By a happy union of both sorts, this style of engraving is carried to a high degree of perfection, and is particularly adapted to express the colouring of the air, where large surfaces are often represented of one tint. In France and Switzerland, the *roulette* is used —a little wheel or roller of steel, with a rough surface and several prominences, which when it is rolled back and forth on the plate, deepen the excavations made by the acid. They have roulettes of all degrees of size and fineness, to make deeper or more shallow impressions on the plate. From time to time the particles separated by this process are removed with a scraper. The aqua tinta mode was first introduced a short time since into England and Germany; and the English, particularly since Gilpin brought the art into notice, have adorned their literary works in this manner.

Aqua Tofana; a poisonous liquid, which excited extraordinary attention at Naples at the end of the 17th and beginning of the 18th centuries, the history of which however is obscure. Tofana, a Sicilian woman, seems to have invented it. According to Lobat, after she had murdered many hundred men, she fled to a convent, although on the discovery of her guilt she was strangled. Keyssler, on the contrary, affirms that she was still alive in prison, 1730. The drink is described as a transparent, tasteless water, of which five or six drops are fatal, producing death slowly, without pain, inflammation, convulsions, or fever. Gradual decay of strength, disgust of life, want of appetite, and constant thirst, were the effects, which soon changed to an entire consumption. That the exact day of death can be predicted, is a mere fable. The strangest stories with regard to its composition have gone abroad. A solution of crystallized arsenic seems to have been the chief ingredient, to which something else was added, probably to conceal the presence of it.

Aqueduct (Latin, *aquæductus*); a conveyance of any kind made for conducting water. The Greeks did very little towards the construction of aqueducts and roads. The Romans, on the contrary, who were more persevering, and had abundant resources of men and money, made prodigious structures of both kinds. Some of the immense aqueducts of the Romans are still in use; some, in the state of ruins, are among the greatest ornaments of Italy. In other ancient countries, also, large aqueducts were built; under Sesostris, in Egypt; under Semiramis, in Babylonia; under Solomon and Hezekiah, among the Israelites. The consul Sextus Julius Frontinus, who had, under the emperor Nerva, the direction of the aqueducts, has written a treatise on this subject—*De Aquæductibus Urbis Romæ*—and is of opinion that they are the most distinguishing proofs of the grandeur of the empire. He mentions nine aqueducts, which had 1594 pipes of an inch and upwards in diameter. Aqueducts were either formed by erecting one or several rows of arcades across a valley, and making these arcades support one or more level canals; or by piercing through mountains, which would have interrupted the water-course. When the aqueduct was conveyed under the ground, there were openings at about every 240 feet. Some of the Roman aqueducts brought water from the distance of upwards of sixty miles, through rocks and mountains, and over valleys in places more than 190 feet high. The declivity of the aqueduct, according to Pliny, was 1 inch, and according to Vitruvius, ½ a foot in a hundred. The censor Appius Claudius Crassus Cœcus, the builder of the great road which was called after him, caused the first aqueduct to be built at Rome, the *Appia Aqua*. Frontinus, as we stated, mentions nine, Procopius 14, and P. Victor 24 aqueducts; some of which were one, some two, some even three stories high, and many miles long. In almost all countries where the Romans extended their conquests, aqueducts were built; thus we find the remains of them in France, Spain, and Asia. The principal Roman aqueducts now remaining are the *Aqua Virginia*, repaired by Pope Paul IV., and the *Aqua Felice*, constructed by Sextus V. In modern times, that of Segovia may be compared with the most admired works of antiquity. At a recent period, there remained 159 arcades, wholly consisting of enormous stones joined without mortar. Louis XIV. began an aqueduct, in 1684, near Maintenon, to carry water from the river Eure to Versailles; but the works were abandoned in 1688. This would have been, perhaps, the largest aqueduct in the world; the whole length being 60,000 fathoms, the bridge being 2070 fathoms in length, 220 feet high, and consisting of 632 arches.

Under this head we must not omit to notice Mr. Telford's great work, the aqueduct of Chirk in Denbighshire. It consists of ten arches, supported by pyramidical piers of stone, and extending about six hundred feet in length. The height of the central arch is about sixty-five feet above the level of the water. Chirk aqueduct is intended for carrying on the navigation of the Ellesmere canal, and is surrounded with some very beautiful and picturesque scenery. Its general effect is well given in the accompanying engraving.



Arabesque, or Arabesk, something done after the manner of the Arabians. *Arabesque, Grotesque*, and *Moresque*, are terms applied to paintings, ornaments of friezes, &c. where there are no human or animal figures, but which consists wholly of imaginary foliages, plants, or stalks. The term is derived from the circumstance that the Moors, Arabs, and other Mahometans only use these ornaments; their religion forbidding them to make any images or figures of men or other animals.

Arack, or Rack; a strong spirituous liquor,

distilled from rice, sugar-cane, or the juice of the cocoa-nut. The last, which is the best, comes from Batavia; the others, from Goa. At Goa, there are three kinds, single, double, and treble-distilled. The double is most sought, although weaker than the Batavian. By stat. 11 Geo. I. c. 30, arack may be seized on board a ship within the limits of any British port.

Aræometer. This instrument is more for curiosity than absolute utility. It was known to Archimedes, who used it for the same purpose as we employ the hydrometer. Some instruments, such as that employed by the French chemist Beaumè, and which is occasionally used in France under the name of *Aréometre de Beaumè*, consist of a small pear-shaped bulb, and a stem graduated in equal parts, which on immersion give the density of the fluid, by a reference to the scale.

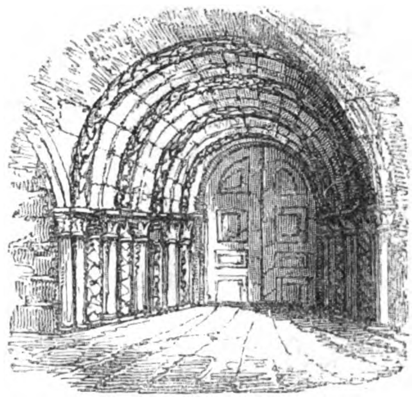
Arc, in *Geometry*, any part of the circumference of a circle or curved line, lying from one point to another, by which the quantity of the whole circle or line, or some other thing sought after, may be gathered.

Arch. A building formed of a segment of a circle, used for bridges, covering apertures, &c., supported by piers, columns, or abutments. The most usual denominations of arches are circular, elliptical, cycloidal, parabolical, hyperbolical, catenarian, equipollent, equilibrial, &c., according to their figure or quality. There are also semi-circular, semi-elliptical, segmental, and compound arches, of various denominations. Circular arches are of several kinds, according to the different parts of a circle. A simi-circular arch is composed of half a circle; a scheme, or segmental arch, is any segment less than a circle; and Gothic, or pointed arches, consist of two circular arcs eccentric, and joined in an angle at the top, each being one-third, or one-fourth, &c. of the whole circle. Elliptical arches are formed of a portion of an ellipsis, and are, in the opinion of some mathematicians, the best calculated for the construction of bridges, as they look bolder, are stronger, and require less materials and labour than the others. Cycloidal arches are constructed of the cycloidal curve, and reckoned, by Dr. Hutton, the best, after the ellipsis, for the above purpose. The learned Doctor reckons the circle next. And as to the others, the parabola, hyperbola, catenaria, &c., he says they should not be at all admitted into the construction of bridges of several arches; but may in some cases be used for a bridge of a single arch which is to rise very high, because then they are not much loaded on the haunches.

A popular view of the principal architectural forms of the arch, as leading to the date of any ancient edifice, will here be found of considerable use, and we cannot do better than quote some striking examples from a very valuable popular work, published by a branch of the Society for promoting Christian Knowledge.

The doors and windows of old English churches, generally, have pointed arches; and from the shape of these arches principally, though there are other minor distinctions, the age of the building may be most accurately inferred, as they have varied in height and width from age to age.

Before the introduction of the English or pointed arch, the circular or rounded arch was in use; and a few very beautiful examples of this kind of building still remain in different parts of the country. It is called Saxon or Norman, from its having prevailed during the reign of the Saxon and Norman kings in England. It commenced at the establishment of Christianity among the Saxons, in the 6th century, and continued to about the year 1135, in the reign of king Stephen. The entrance to the Temple Church, London; the Abbey Gate, Bristol; and the Church of Romsey in Hampshire, are in this style of architecture. The doors in this style are sometimes quite plain, and sometimes very richly carved. The accompanying engraving is from the Temple Church.

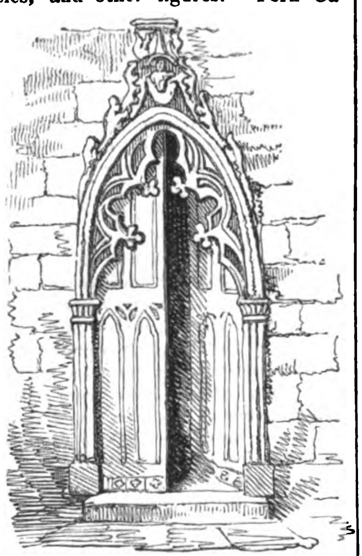


Between the reign of Stephen and that of Henry III., the circular arch began to diappear; and before the death of the latter monarch, gave way to the pointed arch. At first the two arches were intermixed; and the style was then called, *semi, or half-Norman.* Some suppose that the pointed arch was introduced from the Saracens, by the Crusaders to the Holy Land, and from this circumstance they call it the Saracenic arch; but the greater number of persons imagine it to have arisen from the accidental intersection of several rounded arches with each other. That this will produce pointed arches of different widths and heights, according to the points of intersection, may easily be shown by placing two hoops or rings across each other, allowing one point of the hoops or rings to rest upon a floor or table. The crossings of the boughs of trees in an avenue also afford a familiar illustration of the same fact. In the Temple Church the two arches may be found united, and other specimens may be seen in the Church of St. Cross near Winchester; the ruins of Buildwas Abbey, Shropshire; Fountains Abbey, Rievaulx Abbey, and Roche Abbey, in Yorkshire.

When the circular arch totally disappeared in 1220, the *Early English Style* commenced. The windows of this style were at first very narrow in comparison with their height: they were called lancet-shaped, and were considered very elegant: two or three were frequently seen together, connected by dripstones. In a short time, however, the windows became wider, and divisions and ornaments were introduced. Sometimes the same window was divided into several lights, and frequently finished at the top by a light in the form of a lozenge, circle, trefoil, or other ornament. A specimen of this kind may be seen in the beautiful church of St. Saviour's, Southwark, which has lately been thrown open to view by the improvements connected with the erection of the New London

Bridge, and another and a very beautiful example in the "Lady Chapel," which is in course of repair. With reference to the formation of this arch, it is curious to examine the extreme accuracy with which the masonry is connected at the springing of the arch. It is in this respect much superior to that of a later period. The door of St. Mary's, Lincoln, is also in this style, of which we subjoin an example.

About the year 1300, the architecture became more ornamental, and from this circumstance received the name of the *Decorated English Style*, which is considered the most beautiful for ecclesiastical buildings. The windows of this style are very easily distinguished: they are large and wide, and are divided into several lights by mullions, which are upright or perpendicular narrow columns, branching out at the top into tracery of various forms, such as trefoils, circles, and other figures. York Cathedral affords a fine specimen of this sort of architecture, and there is a beautiful window of the same style in the south transept of Chichester Cathedral. The West front of that of Exeter is another specimen, and the door-way of Lincoln Cathedral is in this style, of which we have a delineation in the annexed engraving.



The transition from the *Decorated* to the *Florid* or *Perpendicular Style*, was very gradual. Ornament after ornament was added, till simplicity disappeared beneath the extravagant additions; and about the year 1380, the architecture became so overloaded and profuse, that it obtained the title of ***Florid***, which by some persons is called the ***Perpendicular***, because the lines of division run in upright or perpendicular lines from top to bottom, which is not the case in any other style. King's College Chapel, Cambridge, begun in the reign of Henry VI., though not finished till some time after; Gloucester Cathedral; Henry VII.'s Chapel at Westminster; St. George's Chapel at Windsor; Wrexham Church, Denbighshire; and the Chapel on the Bridge at Wakefield, Yorkshire, are all of this character. Many small country churches are built in this style; and their size not admitting of much ornament, they are distinguished from structures of a later date by mouldings running round their arches, and generally by a square head over the obtuse-pointed arch of the door. A peculiar ornament of this style is a flower of four leaves, called from the family reigning at that period, the Tudor flower.

Architecture. This beautiful and important branch of the fine arts, combines within itself painting, sculpture, building, and some of the higher portions of mathematical science. Michael Angelo Buonarotti, the great founder of modern architecture, possessed these attainments in a very eminent degree, and was consequently enabled to leave to posterity a monument of his art, unequalled by any but that of our own countryman Wren. And if we go back to a still earlier period, we shall find that most of the great edifices of antiquity required as intimate an acquaintance with the exact sciences, as with the merely ornamental branches of design. Of the paramount importance of architecture little need be said, whether we consider it, as some have done, as a mechanical science, sheltering beneath its ample wing the several employments of masons, carpenters, smiths, and all those artizans whom modern refinement has rendered necessary for the enjoyment of life, or as a fine art, exercising the highest powers of the human mind, and becoming the parent and preserver of painting and sculpture, whose very existence may be said to depend upon it.

The history and progressive improvements in architecture will in the first instance engage our attention, and we may then with advantage to the reader furnish a series of popular illustrations of the main distinguishing features of the various "styles" which have been resorted to from the earliest recorded period.

Whatever celebrity the wonders of Babylon attained amongst the ancients, no remains of them have come down to us, and it is the massive edifices of Egypt, built apparently rather for eternity than time, that now excite our admiration as the most ancient as well as stupendous structures existing upon earth. We must not, at this period, omit to notice the remains of Indian and Mexican greatness. But for the splendid ruins at Delhi and Agra, and that most singular specimen in the island of Elephanta, we should scarcely have known of the existence of civilization among the ancient Hindoos; and the aborigines of Mexico were regarded as little better than savages, before the late discoveries by Mr. Bullock. The dates of these buildings are wholly unknown; but from the general similarity they bear to those of Egypt, it is supposed they are of at least equal antiquity. About the same general date may also be classed the architecture of the Hebrews, or, as more properly characterized, the Phœnician style, the greatest mo-

nument of which was the far-famed temple of Solomon. The description of this in the sacred text, will be found on an accurate consideration, to bear great resemblance to that of many of the Egyptian temples. From the Egyptians, the art, such as it was, was learned by the Greeks; but under the protection of that extraordinary people it reached a perfection unheard of before, and, in its peculiar style, unequalled since. The earliest edifices of Greece, however, were by no means remarkable for beauty, the temples in the time of Homer, being little better than rude huts, sheltered, if sheltered at all, by branches of laurel and other trees.

On the decline of Greece, and its conquest by the Romans, the art appears to have been transferred to the conquerors; but among that hardy and warlike race, it made little progress before the age of Augustus. Under the protection of that munificent monarch it rapidly attained to almost as great perfection as in the favoured country of the arts, and the "eternal city" owes much of its present estimation to the noble structures erected by him and his successors. With Rome, however, the art decayed, and was overwhelmed in the general confusion and oblivion of learning, art, and science.

The attention of the Saxons in our own country, probably about the eight century, was excited by the remains of edifices raised by the Romans during their residence in England. These, in their newly-erected churches, they aspired to imitate, but their workmen, ignorant of the principles which guided the architects of those splendid ruins, produced only the general outlines of their patterns, and those clumsy forms continued to be practised with little alteration till the end of the twelfth century. But now, as the tumult excited by the invasion subsided, and the genius of the nation improved, a taste for the fine arts began to show itself, and architecture assumed a different and novel aspect. Instead of tamely treading in the steps of their predecessors, the architects of those times devised a style as scientific as it was grand, and as beautiful as new.

But we must not, while eulogizing those who have adorned our own country with such admirable structures, forget the merits of their contemporaries on the continent · of these it seems to be generally acknowledged, that the French preceded us in point of time, and the Germans excelled us in the size of their edifices : yet no one, on comparing with an impartial eye the several buildings, will hesitate to allow, that in purity of style, variety of design, and delicacy of execution, the English cathedral, and other churches, are not surpassed by those of any nation in Europe; and it is a remarkable fact, that English architects and workmen were employed in many of the finest works on the continent.

We must now turn our attention to Italy : it is worthy of notice, that the Gothic style never came to so great perfection in this country as in the neighbouring nations. Perhaps this was owing to the number of Roman buildings remaining amongst them, and the liberal use they made of their fragments, which is shown even in the finest specimen they possess, Milan cathedral. It is not therefore surprising that the Italians should be the first to reject the style altogether. Indeed, there were instances, in the darkest times, of recurrence to the purer models of antiquity, but these met not the public taste, and were born only to die.

The church of the Apostles at Florence, which was built by Charlemagne in A. D. 805, appears to have been the first effort to revive the forgotten architecture of ancient times, and possessed so much merit, that Bruneleschi, 600 years afterwards, disdained not to accept it as a lesson in one of his own edifices. Two hundred years passed away, and the church of St. Miniate, in the same illustrious city, momentarily recalled from its apparent oblivion this elegant style. The same period again elapsed, and the genius of Cimabue arose to dispel the mists which had so long enveloped the arts of his country. His attention, though principally devoted to painting, was like that of most of the great artists of his time, occasionally turned to the sister arts, and it was partly by his instruction that Arnolpho Lapo became the wonder of the age. The father of this eminent architect, James, was a German by birth, but resided at Florence, where he built the convent of St. Francis, and received the surname of Lapo from the citizens for his skill in architecture. The son, Arnolpho, built the cathedral of St. Marie del Fiore, the largest church in Christendom next to St. Peter's. Although this was principally in the Tedeschi style (the appellation given by the Italians to the debased Gothic of their country), yet so uncommon was the skill displayed in its erection, that the dome being left unfinished by the death of the architect, a century and half elapsed before another could be found to raise it. This was Bruneleschi, who died in the year 1444, and may be considered as the reviver of the classical architecture. His principal work was the Palace Pitti in his native city.

It might have been expected that Rome, which possessed so many fine specimens, would have been the first to show to the world her sense of their value, by encouraging their imitation; but it was not till the middle of the fifteenth century that Pope Nicholas the Fifth showed the first symptoms of reviving taste, by the encouragement of Leon Baptista Alberti (the earliest modern writer on architecture) and Bernardo Rosilini. These, however, were principally employed in repairs, and the erection of fountains, and to Bramante must we concede the honour of being the first who materially adorned this city by his designs. With the then Pope, the memorable Julius the Second, he was much in favour, and it is supposed that it is in a considerable degree owing to this architect that that magnificent pontiff formed the resolution of rebuilding the cathedral of St. Peter in a style suited to the importance and magnificence of the see. In the lifetime of Bramante, however, little was done of this stupendous work; for such was the conception of the architect's collossal imagination, that, although in its present state its section is about double that of St. Paul's at London, it was reduced by his successor, Balthazar Peruzzi; and more considerably by the next who took it in hand, Antonio di San Gallo. These architects, however, while they exerted their talents on paper, proceeded little with the work, and it was left for the sublime genius of Michael Angelo permanently to fix the design of this masterpiece of art, and prince of Christian churches. The edifice, as we now see it, is principally his, except the front, which is considered inferior to the other parts. This work completed, the example thus set by its principal cities was quickly followed in all parts of Italy, which thus gave employment to the talents of Pirro Ligorio, Vignola, Dominico Fontana, Michael San

Michael, Falconetti, Sansovino, Serlio, Barbaro, Scamozzi, and Palladio.

The pure taste which characterized most of these architects, however, was not of long duration. The celebrated artist, Bernini, was one of the first who violated their precepts. He was educated at Rome as an architect and sculptor, and it is related of him, that returning to his native city late in life, with a large fortune, the product of his talents, he was much struck with some of his early works of the school of Michael Angelo and Palladio. He could not but contrast their elegance with the affected graces of the style he had given into, "but," exclaimed he, "had I continued in this manner, I should not have been what I am now." Contemporary with Bernini was Borromini, who was yet more depraved, and was so jealous of the former's fame, that he stabbed himself. After these, Italy cannot boast of any great architects, and we must now return to our native country, as more interesting to its inhabitants, and indeed of more importance in our history than France, or the other nations of Europe.

From the time of Edward the Third, there was a visible decline in the style of English architecture, which lost itself in a profusion of ornaments, more attention being paid to the details, than to the general forms of the buildings. By the time of Henry the Eighth this increased to a great extent, and the chapel erected by his father at Westminster was one of the last buildings which showed any taste in the style. This depraved manner naturally excited disgust in the minds of those persons who had seen the purer style then prevailing in Italy, which, as might be expected, they endeavoured to introduce. The nation, however, had been too long accustomed to the Gothic readily to surrender it, and during the reigns of Elizabeth and James, the mixture of, or compromise between, these styles produced a most barbarous result. But this could not last long: the prejudices of the people in the course of time gave way, and Italian architecture in all its purity was first executed in this country by Inigo Jones.

The father of modern English architecture was born about 1572, and died in 1652. At the expense either of the Earl of Pembroke or the Earl of Arundel, he travelled into Italy, and from an examination of the elegant buildings in that country, both of ancient and modern erection, he imbibed a taste for architecture, which he put in practice with great success on his return to England. His first work in this country was the interior of the church of St. Catherine Cree in London, and his most considerable design, the projected palace of Whitehall, the part of which that is executed, the Banquetting-house, is barely one-fiftieth part of that magnificent idea. After the death of Jones no considerable architect appeared, till the talents of Sir Christopher Wren (before that time devoted to philosophy and general learning) were called to the aid of the languishing art. He was born in the year 1632, and died at the age of ninety-one, in 1723, after being, in his eighty-sixth year, unfairly dismissed from the office of surveyor-general, which he had held with unparalleled ability fifty-one years. When that temporarily disastrous, yet permanently useful event, the fire of London, occurred, this great man was almost solely employed in rebuilding the numerous public edifices destroyed by the conflagration, and chiefly the cathedral of St. Paul; his execution of which arduous task, whatever be the objections raised against parts of it, by the taste of some, and the jealousy of others, remains a lasting monument of his genius in decorative, and unexampled skill in constructive architecture.

Before the death of Wren appeared Sir John Vanburgh, who was employed by the nation to erect that monument of national gratitude, Blenheim House. Both the architect, and this, his greatest work, were alternately censured and neglected, till Sir Joshua Reynolds vindicated his fame in his lectures to the Royal Academy. Next in order were Hawksmoor, the pupil of Wren, Lord Burlington, Kent, and Gibbs, of the latter of whom, Mr. Mitford observes, that allowing his talents to be small, how much do we owe to Lord Burlington, that by his precepts such a man was enabled to build one of the finest modern works, St. Martin's Church in the Fields. To Lord Burlington, indeed, it is probable we owe more than is generally considered, for besides the patronage he afforded to the artists of his time, and the assistance he gave them from his own genius, it is perhaps owing to his example, that a general feeling of attachment to the arts was conceived by the young men of rank and fortune in England. The Turkish government, which in its prosperity ruled with a rod of iron the once fertile plains of Greece, began now, in its decline, to relax a little of its ancient rigour, and these gentlemen were thus enabled to extend their travels (which before were bounded by the Archipelago) into this important country. Some of them formed at their return, the Dilettanti Society, for the encouragement of their researches into those (to modern times) new regions. These proceedings could not but excite great interest and curiosity in the public mind, which were fully gratified after some years by Mr. Stuart, who, in a long residence at Athens, made accurate drawings of most of the ancient buildings then existing. These were published in three volumes, folio, to which a fourth was afterwards added by Mr. Revely. The effects of these importations may be seen in every street in London.

The revival of the neglected architecture of the middle ages constitutes a new era in our history. Perhaps the first person who dared to recommend, by writing and example, a style so long in disrepute, was the celebrated Horace Walpole, Earl of Orford, who built the well-known villa of Strawberry Hill, to testify his fondness for it. This was succeeded by Lee Priory, by Mr. Wyatt, who quickly outstripped all the professors of his day, both in this style and the Roman. His greatest work in Gothic architecture was Fonthill Abbey: the purest taste reigned throughout the whole of this splendid structure, and the architect has thus bequeathed to succeeding professors a legacy of incalculable value.

We may now take the subject of architecture somewhat more in detail, and in accordance with our plan, proceed to examine the various "orders," as they are called, commencing with the Tuscan.

The Tuscan Order, as an antique, exists only in the works of Vitruvius, the description in which, being very obscure, has left a wide field for the ingenuity of modern architects. Among these Palladio composed two profiles; one from the description of the ancient master, and the other, according to his own idea of a simplification of the Doric. That of Vignola, however, has been most generally approved and adopted.

The base of this order consists of a simple torus,

with its fillet; it is, as are in general in all the Roman orders, accompanied by a plinth.

The proportions, from Sir W. Chambers, are as follow: the column, fourteen modules; the entablature, three modules, fifteen minutes. Of the former, the base occupies one module; the shaft (including the astragal, which divides it from the capital), twelve modules, and the capital one. Of the latter, the architrave (including the fillet), thirty-one minutes and a half; the frieze, the same; and the cornice, forty-two minutes.

The intercolumniations, in all the orders except the Doric, are the same; viz. the eustyle, which is most common and beautiful, four modules, twenty minutes; the diastyle, six modules; and the aræostyle, seven modules.

The Tuscan order admits of no ornaments, nor flutes in the columns; but rustic cinctures are sometimes represented on the shaft, an example of which occurs in the accompanying illustration, *fig.* 1.

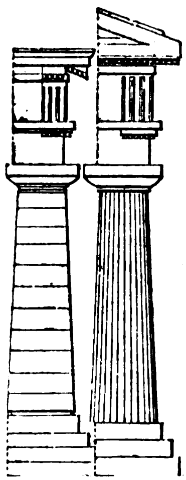


Fig. 1. *Fig.* 2.

This order may be employed in most cases, where strength and simplicity are required, rather than magnificence; such as prisons, market-places, arsenals, and the inferior parts of large buildings.

The Doric Order. We now come to an order, of which numerous ancient examples exist, and which will, in consequence, furnish us with more materials for description than the preceding. It is represented at *fig.* 2. The origin of the *Doric Order* is thus described by Vitruvius:

"Dorus, son of Hellen and the nymph Orises, reigned over Achaia and Peloponnesus. He built a temple of this order, on a spot sacred to Juno, at Argos, an ancient city. Many temples similar to it were afterwards raised in the other parts of Achaia, though at that time its proportions were not precisely established." This account, as well of those of the orders which we shall presently examine, is very incredible, and is now generally rejected.

From theory, however, we must now proceed to fact and description, and will commence with the Doric of the Greeks, referred to by Vitruvius (who nevertheless confounds this with what was commonly executed at Rome in his time). The most perfect example is the order of the Parthenon, or temple of Minerva, in the Acropolis at Athens, erected under the administration of Pericles, who lived about 450 years before the Christian era. We cannot do better than give the dimensions of this singularly fine specimen. The column (including the capital), ten modules, twenty-eight minutes and a half; the whole entablature, three modules, twenty-seven minutes and three-quarters; the capital, twenty-seven minutes and three-quarters; the architrave (with its fillet), one module, twelve minutes and three-quarters; the frieze, to the square member of the corona, one module, nineteen minutes; and the cornice, twenty-six minutes. Diameter of the column at the top, one module, sixteen minutes.

To proceed to the order designated by this title by the Romans. Very few ancient examples of this variation exist. The most perfect is that of the theatre of Marcellus, if, perhaps, we except that misshapen pile, Trajan's column, which is generally pronounced to be Tuscan. It is, therefore, principally indebted for its existence to the modern Italian architects, who, having little of antiquity before their eyes, appear to have bestowed more attention upon this order than the others, and it must be confessed that they have made of it a very elegant design, though, as before observed, essentially different from the original and true Doric. The measures, from Sir William Chambers, are as follow: the base, thirty minutes; the shaft, thirteen modules, twenty-eight minutes; and the capital, thirty-two minutes; the architrave, thirty minutes; the frieze to capital of triglyph, forty-five minutes; and cornice, forty-five minutes. Upper diameter of column, fifty minutes.

In no example of antiquity is the Doric column provided with a base. This circumstance has occasioned no small perplexity to some of those fanciful writers, who seek in every point some analogy to the human figure, or the trunk of a tree. Vitruvius, indeed, has told them that the base is a *shoe*, first invented to cover the nakedness of the matronly prototype of the Ionic order. "But," says Monsieur Le Clerc, "I must own I cannot consider a column without a base, comparing it to a man, but I am, at the same time struck with the idea of a person without feet, rather than without shoes; for which reason I am inclined to believe, either that the architects had not yet thought of employing bases to their columns, or that they omitted them in order to leave the pavement clear, the angles and projection of bases being stumbling-blocks to passengers, and so much the more troublesome, as the architets of those times frequently placed their columns very near each other, so that, had they been made with bases, the passages between them would have been extremely narrow and inconvenient." Accordingly, to supply this defect, as it was considered in this order, most architects have employed the *attic base*, which is common to all the orders except the Tuscan, though belonging, perhaps, more peculiarly to the Ionic.

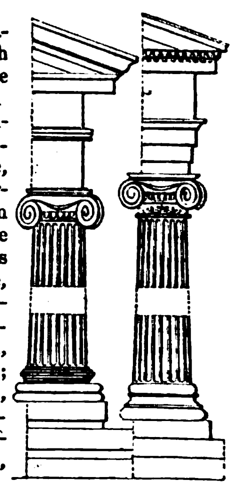
It consists of two tori, with a scotia and fillets, between the upper of which, in this version, resembles an inverted ovolo. The fillet above the upper torus is always connected with the shaft by a curve, as is also that under the capital, for which reason they are commonly considered as part of the shaft. The *plinth*, or square member beneath, is usually understood, in Roman architecture, as an indispensable appendage to the base, though Palladio has omitted it in his Corinthian order; but it is rarely found in the Greek specimens. To save this order, however, from the sad humiliation of being obliged to borrow a shoe when required to wear one, Vignola provided it with this appendage. His base consists of one large torus, with one considerably smaller resting upon it, surmounted by the fillet.

M. Le Clerc has, however, we apprehend, discovered the true reason why, at least in the latter Greek specimens, the base is omitted; namely, the very narrow intercolumniations. In the Greek order alteration is not probable, and perhaps not desirable; but in the Roman, where this addition has been long provided for us, and the intercolumniations adjusted accordingly, the omission would be certainly improper.

The most striking peculiarity in this order is the *triglyph* (supposed by Vitruvius to be the end of the joists laid transversely on the beam of the architrave), which forms the technical distinction between the Grecian and Roman Doric, being in the former always placed at the corner of the entablature, and in the latter, invariably over the centre of the column. This circumstance is a corroboration of the objection against the notion of the timber prototype; for, following the idea of the Egyptian origin of Greek architecture, there is found in the large hollowed crown moulding of the temple of Tentyris, a decoration very similar to the Doric triglyph, the extreme parts of which are placed at the angle, like the Greek Doric, but which, from their situation, bear not the least resemblance to the ends of pieces of wood. The triglyph is surmounted by the mutule, in the Greek, and in some Roman examples inclined, but in most modern profiles horizontal: on its soffit are represented guttæ, or drops. The spaces between the triglyphs on the frieze, are called metopes, which, in the modern Doric, are invariably perfectly square, and generally enriched with sculptures. Those which formerly adorned the metopes of the Parthenon were brought to this country by Lord Elgin, and now form the principal part of the collection which is known by his name at the British Museum. In the modern order these sculptures are most commonly an alternate bull's scull, and patera. The extreme projections of all these ornaments should be less than that of the trilgyph itself, thus keeping a due subordination between mere decorations and essential parts. All the Grecian Doric columns are fluted, and in both Greek and Roman this is performed without fillets between, as in the other orders. The intercolumniations in this order differ from those of the others, on account of the triglyph, the metopes being required to be exactly square. They are as follow: the coupled columns of course must stand under adjoining triglyphs; this make their distance, at the foot of the shaft, twenty-one minutes. The next intercolumniation is the monotriglyph, having *one* between the columns; the distance is three modules. The diastyle—two triglyphs, five modules and a half. The aræosistile, which has three between, eight modules.

The Ionic Order. The account of this order, which is given by Vitruvius, informs us, that in a general assembly of the Grecian states, thirteen colonies were sent over into Asia, by the Athenians; the expedition being led by Ion, whom the Delphic oracle which directed the emigration had acknowledged for the offspring of Apollo. They settled on the borders of Caria, and built several cities of great fame, of which were Ephesus, Miletus, Samos, and Colophon, to which Smyrna was afterwards added: and after the expulsion of the original inhabitants, these colonies were denominated Ionian, from the name of their chief. "In this country," continues he, "allotting different sites to sacred purposes, they erected temples, the first of which was dedicated to Apollo Panionius. It resembled that which they had seen in Achaia, and, from the species having been first used in the cities of Doria, they gave it the name of Doric. As they wished to erect this temple with columns, and were not acquainted with their proportions, nor the mode in which they should be adjusted, so as to be both adapted to the reception of the superincumbent weight, and to have a beautiful effect, they measured a man's height by the length of the foot, which they found to be a sixth part thereof, and thence deduced the proportion of their columns. Thus the Doric order borrowed its proportion, strength, and beauty from the human figure. On similar principles they afterwards built the temple of Diana, but in this, from a desire of varying the proportions, they used the female figure as a standard, making the height of the column eight times its thickness, for the purpose of giving it a more lofty effect. Under this new order they placed a base as a shoe to the foot. They also added volutes to the capital, resembling the graceful curls of the hair, hanging therefrom to the right and left certain mouldings and foliage. On the shaft, channels were sunk, bearing a resemblance to the folds of a matronal garment.* Thus were two orders invented, one of a masculine character, without ornament, the other approaching the delicacy, decorations, and proportion of a female. The successors of these people improving in taste, and preferring a more slender proportion, assigned seven diameters to the height of the Doric column, and eight and a half to the Ionic. The species, of which the Ionians were the inventors, received the appellation of Ionic."

The most beautiful Grecian specimens of this order are the temple on the Ilyssus, and the temples of Neptune Erectheus, and Minerva Polias, in the Acropolis at Athens, the two latter of which are so similar, that we shall not here discriminate between them. We are thus reduced to two Greek examples, and these are so exquisitely beautiful, that it is difficult to give the preference to either. We shall therefore describe both. The temple on the Ilyssus is the plainer of the two: its volute consists of a single spiral with a deep channel between, and is separated from the shaft by the sculptured echinus. The architrave is not broken into fasciæ, as in most other specimens. The cornice consists simply of a square member, with an echinus and fillet surmounted by the cymatium: the bed-mouldings in the elevation are completely concealed. The base is composed of two tori, the upper of which is channelled horizontally, and surmounted by a bead, inclosing a very flat scotia, the upper fillet of which projects as far as the extremity of the torus. The flutes are semi-elliptic.



The following are the measures of this order, of which specimens are shown in the engraving. The column, including base and capital, sixteen modules, fourteen minutes and one-fifth; the base, twenty-nine minutes and four-fifths; the capital (to bottom of volute), forty minutes. The architrave, fifty-five minutes and two-fifths; the frieze, forty-nine minutes; the cornice, thirty minutes and one-fifth. Width of the capital, three modules, three minutes; upper diameter of column, fifty-one minutes. Intercolumniation from centre to centre of column six modules, five minutes and two-fifths.

* All the Grecian Doric columns have flutes; a fact Vitruvius does not appear to have been aware of.

The specimens furnished in the temple of Minerva Polias are next to be considered. This example is much richer, yet no less elegant than the other: the volute, instead of a single spiral, is formed by three: the sculptured echinus beneath is surmounted by a guilloched moulding, and separated from the shaft by a neck adorned with honey-suckles. The base is very similar to that of the temple on the Ilyssus, except that its beauty is increased by the diminution of its height, the scotia is deeper, and the upper torus is guilloched. The architrave consists of three fasciæ, and the cornice is similar to that of the Ilyssus temple, except that the echinus and bed-moulding are sculptured, and the astragal of the latter is seen in the elevation beneath the corona.*

The column, including base and capital, is eighteen modules, seven minutes and one-tenth in height; the base, twenty-four minutes; and capital, forty-two. The architrave, forty-five minutes and one-fourth; the frieze, forty-seven minutes and four-fifths; and cornice (to the fillet of the echinus, which is the greatest *actual* height of the entablature, the cymatum being a restoration), twenty minutes and two-fifths. The width of the capital, three modules, three minutes. Upper diameter of column, forty-nine minutes and a half. Intercolumniation (from centre to centre), nine modules. Both these orders are destitute of insulated plinths.

Having thus given our readers an idea of the finest Greek specimens of this order, we must now proceed to the Roman and Italian version of it. It is the peculiarity of this order, that its front and side faces are dissimilar. To obviate this inconvenience, the Greeks twisted the extreme volutes of a portico so as to make the two faces alike. But Scamozzi, a famous Italian architect, designed a capital in which the volutes proceeded angularly from the shaft, thus presenting the same front every way; and the capital so executed has been generally attributed to the supposed inventor. Sir William Chambers, however, is of opinion that Michael Angelo was the author of one of this description in the Vatican at Rome.† This capital is commonly known as the modern Ionic, but has not been often executed in large works. The frieze of this order has been, by many architects, and Palladio among the number, pulvinated, or rounded in its contour, and smaller than the architrave, as though it were pressed down and bent by the superincumbent weight; but the ill effect of this has been so generally perceived, that it is rarely to be seen in late works. The cornice is distinguished from the Greek by its variety of mouldings, among which the most remarkable is a square member in the bead-mouldings, cut into small divisions, somewhat resembling teeth, whence they are called *dentils*. In other points of variation between the Grecian and Roman architecture there may be a difference of opinion; but with respect to the Ionic capital, we conceive this to be impossible. Whoever compares the meagre, petty form of the capital of the temple of Concord, with that of the Erectheion, must instantly, whatever be his former prejudices, perceive the amazing difference, and unhesitatingly acknowledge the vast superiority of the latter. The poverty of the solitary revolving fillet, the flat, insipid lines, and the enormous projection of the clumsy echinus, combine to render this the very worst feature in all the Italian orders. The base commonly used is the Attic, though Vitruvius has appropriated one to this order, resembling the Corinthian without its lower torus.

The following are the measures of the order from Sir William Chambers: The base, one module; the shaft, sixteen modules nine minutes; and capital, twenty-one minutes. The architrave, forty minutes and a half; the frieze, the same; and cornice, fifty-four minutes. Width of capital, two modules, twenty-six minutes. Upper diameter of column, fifty minutes.

"As the Doric order," says Sir William Chambers, "is particularly affected in churches or temples dedicated to male saints, so the Ionic is principally used in such as are consecrated to females of the matronal state. It is likewise employed in courts of justice, in libraries, colleges, seminaries, and other structures having relation to arts or letters; in private houses, and in palaces; to adorn the women's apartments, and, says Le Clerc, in all places dedicated to peace and tranquillity. The ancients employed it in temples sacred to Juno, to Bacchus, to Diana, and other deities whose characters held a medium between the severe and the effeminate."

The Corinthian Order.—The story of the origin of this order, given by Vitruvius, is as follows: "The third species of columns, which is called Corinthian, resembles in its character the graceful, elegant appearance of a virgin, whose limbs are of a more delicate form, and whose ornaments should be unobtrusive. The invention of the capital of this order arose from the following circumstance. A Corinthian virgin, who was of marriageable age, fell a victim to a violent disorder: after her interment, her nurse collecting in a basket those articles to which she had shown a partiality when alive, carried them to her tomb, and placed a tile on the basket for the longer preservation of its contents. The basket was accidentally placed on the root of an acanthus plant, which, pressed by the weight, shot forth towards spring in stems of large foliage, and in the course of its growth reached the angles of the tile, and thus formed volutes at the extremities. Callimachus, who for his great ingenuity and taste in sculpture was called by the Athenians κατατεχνος, happening to pass by the tomb, observed the basket, and the delicacy of the foliage which surrounded it. Pleased with the form and novelty of the combination, he took the hint for inventing these columns, and used them in the country about Corinth, regulating by this model the manner and proportion of the Corinthian order. A beautiful illustration of this story will be found under Acanthus.

It has been before observed in our notice of Egyptian architecture, that the capitals to be found in that country are much more likely to have given the hint for the Corinthian than the circumstance here mentioned. The only pure example of this order in Greece is the monument of Lysicrates, of which a view is given in a subsequent page. The capital of this specimen is exquisitely beautiful, but the same praise cannot be awarded to the entablature: the architrave is too large, and the frieze extremely small; the bead-mouldings of the cornice (which completely overpower the corona) consist of large dentils, supported by the echinus, and surmounted by a cyma

* This is most beautifully executed at St. Pancras church, at the east end; in the interior the capital and base are carved in marble, with the shaft of scagliola work resembling verde antique. In the portico of this church that of the Erectheion is copied.

† It may be seen in the beautiful circular portico of All Souls' church, built by Mr. Nash in Langham Place.

recta under a cyma reversa, which supports the corona. The base is extremely beautiful, resembling that of the temple of Minerva Polias, except that an inverted echinus is substituted for the upper torus: the base stands upon a large inverted cavetto, connected with the continued plinth by another inverted echinus. The flutes terminate upwards in the form of leaves, instead of being divided from the capital as usual by an astragal. The building is circular, and its centre is the summit of an equilateral triangle, of which the base is a line bounded by the centres of any two of the columns: the intercolumniation is six modules, thirteen minutes and one-fifth. Height of the column, twenty modules, thirteen minutes and two-fifths, of which the base occupies twenty-one minutes; and the capital, two modules, twenty-seven minutes. The architrave, fifty-three minutes and two-fifths; the frieze, forty-one minutes and two-fifths; and the cornice forty-eight minutes and four-fifths. The finest Roman example of this order is that of three columns in the Campo Vaccino at Rome, which are commonly considered as the remains of the temple of Jupiter Stator. This example has received the commendation of all modern artists, yet has seldom been executed in its original form. This is probably owing to the excessive richness and delicacy of it, which renders its adoption very expensive, and perhaps the modification of it by Vignola is preferable to the original, possessing a sufficient enrichment without the excessive refinement of the other. In this order (which has been adopted by Sir William Chambers) the base is one module in height; the shaft, sixteen modules, twenty minutes; and the capital, two modules ten minutes; thus giving ten diameters to the whole column. The architrave and frieze are each one module, fifteen minutes in height, and the cornice, two modules. The cornice is distinguished by modillions interposing between the bead-mouldings and corona; the latter is formed by a square member surmounted by a cymatum supported by a small ogee: the former is composed by dentils, supported by a cyma reversa, and covered by the ovolo. When the order is enriched, which is usually the case, these mouldings, excepting the cymatium and square of the corona, are all sculptured: the column is also fluted, and the channels are sometimes filled to about a third of their height with cablings, which are cylindrical pieces let into the channels. When the column is large, and near the eye, these are recommended as strengthening them, and rendering the fillets less liable to fracture; but when they are not approached, it is better to leave the flutes plain. They are sometimes sculptured, but this should be only in highly enriched orders. An example is given in *fig.* 1.

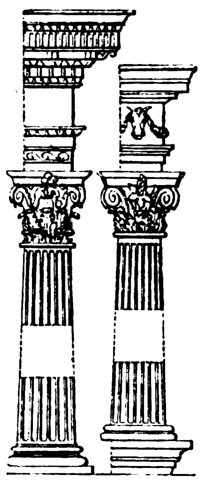


Fig. 1. *Fig.* 2.

The flutes are twenty-four in number, and commonly semicircular in their plan. The Corinthian base is similar to that of the composite order, excepting that two astragals are employed between the scotiæ instead of one; but the Attic is usually employed for the reasons before assigned.

"The Corinthian order," says Sir William Chambers, "is proper for all buildings where elegance, gaiety, and magnificence are required. The ancients employed it in temples dedicated to Venus, to Flora, Proserpine, and the nymphs of fountains, because the flowers, foliage, and volutes with which it is adorned seemed well adapted to the delicacy and elegance of such deities. Being the most splendid of all the orders, it is extremely proper for the decoration of palaces, public squares, or galleries and arcades surrounding them; for churches dedicated to the Virgin Mary, or to other virgin saints, and on account of its rich, gay, and graceful appearance, it may with propriety be used in theatres, in ball or banquetting rooms, and in all places consecrated to festive mirth, or convivial recreation."

The Roman, or *Composite Order*.—This order (though not considered by them as a distinct one) was employed by the Romans principally in triumphal arches, the column and entablature being the same as, or little differing from, the Corinthian.

The difference was, however, sufficient for the Italians to ground a new order upon. The capital, as being *composed* of the Ionic and Corinthian, they termed *composite*, and to justify the application of the name to the order in general, they combined in the entablature the dentils of the Ionic with the mutules of the Doric, and enrichments of the Corinthian, and gave to the architrave but two fasciæ, thus rendering it in some respects more simple, but more enriched than the latter, while the former had little but the name left in the composition. The whole order may be safely pronounced to be heavy, without possessing grandeur, and rich, though destitute of beauty. It has not been frequently adopted, and it is to be lamented that Sir Christopher Wren has made so much use of it about St. Paul's.

The base commonly appropriated to this order is extremely beautiful: it consists of two tori (the lower of which is considerably the larger), with two scotiæ enclosing an astragal. This is called the *proper* base of the order, but the Attic is usually employed, being more simple, and consequently less expensive than the other.

The measures of this order, from Sir William Chambers, are as follow: the base, thirty minutes; the shaft, sixteen modules, twenty minutes; and capital, two modules, ten minutes. The architrave, forty-five minutes; the frieze, forty-five minutes; and the cornice, two modules. A column of this order is shown at *fig.* 2.

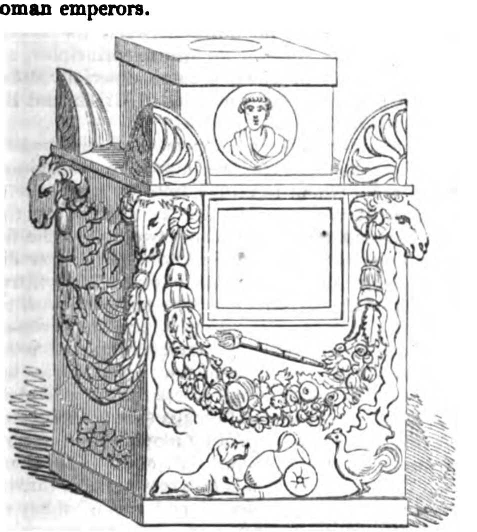
Persians and Caryatides.—Having now described what are called the regular orders, it is necessary to notice in the next place the employment of human figures instead of columns for the support of an entablature. We will first give, as in former cases, the account of Vitruvius. "Carya, a city of Peloponnesus, took part with the Persians against the Grecian states. When the country was freed from its invaders, the Greeks turned their arms against the Caryans, and upon the capture of the city put the males to the sword, and led the women into captivity. The architects of that time, for the purpose of perpetuating the ignominy of this people, instead of columns in the porticos of their buildings, substituted statues of these women, faithfully copying their ornaments, and the drapery with which they were

attired, the mode of which they were not permitted to change."

There are two great objections to the truth of this story: first, that the circumstance is not mentioned by any of the Grecian historians; and secondly, that it is certain animal figures were employed for this purpose long previous to the time assigned by Vitruvius.

Having thus shown our readers what is *not* the origin of these figures, it must next be our business to inform them what *is*, or rather what is most probable, and for this purpose we must trespass on the kindness of Mr. Gwilt, the only writer we believe who has given a satisfactory account of them. He conjectures the name to have arisen from the employment of them in temples to Diana, who is supposed to have made the Lacedæmonians acquainted with the story of Carya (turned into a nut-tree by Bacchus, who also transformed her sisters into stones), and thence worshipped by them under the name of *Caryatis*. Thus, being first employed in temples dedicated to this goddess, they afterwards came into use in other buildings as representations of the nymphs who assisted at the mysteries of the patron goddess. They may be seen at St. Pancras Church, correctly copied from the Pandroseum. An example is given in the accompanying wood-cut of an older date, though the figure is much more beautifully formed.

The ancient cenotaph or tomb furnished some of the most beautiful displays of architectural ornament, executed either by the Greek or Roman sculptors. We furnish one erected to the memory of one of the Roman emperors.



The ornaments were all of a funeral character, and there is reason to suppose that the above cenotaph differed from many of a nearly similar character, inasmuch as it was intended to hold the remains, instead of being merely an honorary memento.

The ornaments, it will be seen, consist of heads supporting wreaths of flowers. Speaking of this species of ornament, Mr. Kempe observes in a late volume of the *Archæologia*, "garlands were so much used by the ancients at their sacrificial and social feasts, that as the patines for libation, and the sculls of victims, from being at first suspended on the friezes of their temples, became at last sculptured on them in stone, so were the vegetable wreaths at length transferred in a similar manner." We quote Mr. Kempe, as he is a good antiquary and a learned scholar; and there is but little doubt but that the greater part of the architectural ornaments of this character had their origin on altars and monuments, and were from thence transferred to the portico, frieze, and column of the temple.

We may now furnish an exemplification of the use of the column in one of the most beautiful monuments of Grecian architecture extant. We allude to the choragic monument of Lysicrates, a portion of which is shown in the accompanying engraving.

This edifice, which is usually, but erroneously, termed the "Lantern of Demosthenes," stands near the eastern end of the Acropolis. It consists of a circular colonnade supporting a *tholus* or cupola, with the highly enriched foliage ornament represented in the figure. Illustrations of complete edifices in the various styles we have described in the course of this article, will be found in another portion of our work, and we now at once proceed to that which has not unaptly been called the English Style or order.

It has been before observed, that the rude buildings of the Saxons and Normans in this country, which are evidently copied from those of the Romans, may, by gradual improvement, have given rise to Gothic architecture; and that this was the case in England at least there is no doubt. But there are certain peculiarities even in these crude and imperfect attempts (though afterwards more fully developed) which require to be noticed before we proceed further, plainly indicating that the works in question were raised under the influence of a less ardent sun, and more obscured sky. In the happy climate of Greece, where little was to be feared from change of

weather, the temples (the only buildings much distinguished for architectural excellence) were frequently destitute of covering. Windows, in this case, being entirely superfluous, the walls were, in many instances, pierced only by a single door, which served at once for ingress and egress both to priests and worshippers. Science here, therefore, was not needed, and indeed is not to be found. With the practical application of the principle of the arch the Greeks do not appear to have been acquainted; the large stones, which in those early ages were to be procured in abundance, being sufficient to cover the columns and the opening of the doors. As architecture improved, however, roofs were added to these edifices, and to throw off the rain they were inclined downwards from the centre to the extremities. This inclination, in a climate where so little rain or snow fell, required to be but small; but in Rome, which is more northern, it was found convenient to increase it to meet the exigencies of the situation. In countries far more exposed to vicissitudes of weather than either of these, it is evident that a very different pitch will be requisite, and this theory is verified by the buildings of northern climates, the architects of which, though totally unacquainted with the works of their southern predecessors, by a singular coincidence adapted their roofs to their latitude in a regular scale of gradation from them. The Saxon and Norman architects, though they did not comprehend this principle in the perfection to which it was afterwards carried, were sensible of the wants of the climate, and made their roofs much higher than those of their Roman prototypes.

This circumstance presenting itself to minds so quick to perceive, and so able to adopt, any novelty which came recommended by utility and beauty as those of the architects of the middle ages, could not fail of meeting with the highest attention. It was soon seen that unbroken vertical lines and lofty buildings were necessary to harmonize with the high pitched roof, and the pointed arch is but a natural and easy deduction from these *data*.

But there is another and an important peculiarity in buildings designed for northern climates to which we must next call the reader's attention. This arises from the numerous circumstances which in these regions conspire to obscure the rays of the sun. The great darkness which prevails in them, compared with the countries of Greece and Italy, evidently requires a very different arrangement in the public buildings, and this circumstance has received no small share of the attention of the architects whose works we are considering. The variety and beauty of its windows is not the least striking peculiarity of Gothic architecture, and indeed they form the readiest criterion for distinguishing the several styles, as we have already seen in the *art.* Arch.

A third essential point of distinction between this style and all others, consists in the different *purposes* for which the edifices in which it is most apparent were constructed, and the different *ceremonies* for which they were adapted. Although the rites of Greek and Roman paganism were numerous and splendid, they required little aid from architecture: the ceremonies with which they were connected were principally performed in the open air, and the temple was only used as a receptacle for the statue of the deity, before which sacrifices were offered, and prayers preferred.

But Christian worship under papal guidance, and in a country where the atmosphere was so cold as to render shelter requisite for the performance of its ceremonies, required other arrangements in the edifices dedicated to it: for its numerous and splendid processions, was provided a long, narrow, and lofty gallery, called *the nave;* for the reception of the multitude to witness these, adjacent wings were added, called *aisles.* A *choir* was added for the actual performance of the sacred rites, and numerous *chapels* to commemorate the bounty of individuals were dispersed about the edifice.

All these essential appendages necessarily occupied a space of great magnitude, and the figure of the *cross,* held by the Romish Church in the most profound veneration, was pitched upon to regulate the general form of the building thus constituted. Our reason for mentioning these particulars is, to show the absolute necessity which thus arose for a degree of science and mathematical knowledge, not dreamt of by the architects whose works are received as the sole standards of excellence by most of the professors of modern times. The narrow intercolumniations of the Grecian buildings would have been ill adapted for the display of feudal magnificence, and the stones within the reach of the builders were far too small to have covered even these. Thus the arch became unavoidably a prominent feature in the style. To give greater magnificence to the nave it was made a story higher than the aisles. The wall of this upper story is supported by a tier of arches supported by large piers, which divides the nave from the aisles. The upper, or *clere* story, as it is called, has windows answering to those beneath. To form an interior roofing which should at once hide the timbers above and furnish an appropriate finish to the architecture, the same contrivance was resorted to, and from this cause have proceeded those vast monuments of daring ingenuity which, while they excited the admiration, have baffled the rival attempts of modern architects.

Having thus traced, we hope, perspicuously and satisfactorily, the causes which gave rise to Gothic architecture, and led to its perfection; it will be proper, before discriminating between its several styles, to explain some of its leading principles, and those particulars in which it more especially differs from the better known principles of Greek and Roman architecture.

Of these, the first in importance is the pointed arch, of which there are three kinds. 1. The simple pointed arch, which is struck from two centres on the line of the impost. 2. The Tudor arch, or that which has four centres, of which two are on the line of the impost, and the other two at any other distance. 3. The ogee, which has likewise four centres, two on the impost line, and two on a line with the apex, the segments struck from which are reversed. This form is used only in tracery, or small work, except as a canopy or dripstone over doors and windows. The pointed arch differs from the semicircular, as employed by the Romans (besides its form), in having its soffit occupied by mouldings of various projections, instead of being flat, enriched with panels. The cause of this is its great breadth (having frequently to support a wall and roof), which required the piers to be of corresponding magnitude, to diminish the unpleasing effect of which, the architects surrounded them with slender shafts. The

projections of these being carried into the arch, caused it to be of the form in question. It is scarcely necessary to add, that these piers are always undiminished. Arising from the general use of the arch is that of the buttress. In Norman work this was avoided by the employment of walls of vast thickness, with very small windows; but when architecture began to assume a lighter character, the windows were enlarged, and the thickness of the walls diminished. To compensate for this deficiency, the buttress was employed, at once to resist the pressure of the arches within, and to prevent the necessity of the walls being of an unwieldy thickness. These are often divided into stages (each being of less projection than that beneath it) finished by pinnacles, and from the upper part of them spring insulated arches, serving as a protection for the clere story.

The next thing to be mentioned is the *steeple*, with its component parts and accompaniments. When square topped, it is called a tower, which is often crowned with a spire. Slender and lofty towers are called *turrets*, and are commonly attached either to the angles of a large tower (when they frequently contain staircases), or to the angles of a building. They are sometimes surmounted by spires, a beautiful example of which may be seen at Peterborough Cathedral, in the turret at the north-west angle. In this exquisite and unique design the turret is square, and decorated at the angle with boltels, which are carried up beyond it, and finished by a triangular pinnacle. The spire in the centre is octagonal, and rectangularly placed within the square, four of its sides thus forming triangles with the angular boltels, which being arched over, form grounds for pinnacles of the same form, which are carried up to about half the height of the spire itself. The effect is beautiful beyond description, and merits the most attentive examination.

Next in importance are the *windows* of Gothic architecture, but as these differ so widely in the several styles as to form the readiest criterion for distinguishing them, they will be more properly noticed when we speak of these styles. We shall pursue the same plan with the doors, and other subordinate parts.

It may be proper in this place to say something of the *mouldings* of Gothic architecture. Of these, that which bears the most resemblance to the Roman mouldings is the *ogee*, distinguished by the same name, or that of cyma reversa, in the nomenclature of the Italian school. A moulding used for the same purpose as the cyma recta, and much resembling it, is also found, more frequently perhaps than any other. That which is most peculiar to the style, is the *boltel*, or cylindrical and nearly detached moulding, often answered by a corresponding hollow, which forms one of the happiest species of relief which could have been resorted to.

We shall now detail the different styles of Gothic architecture, with the peculiarities of each, and in so doing, follow the arrangement and nomenclature of Mr. Rickman, the only writer who has attempted to give a clear and practical account of this beautiful though neglected style. He distinguishes three variations, which may, without impropriety, be called the *orders* of Gothic architecture; differing, however, from the Greek and Roman orders in this circumstance; that while they are confined to one part of a building, or at most, affect the rest only in regard to strength or delicacy, these extend through every part of the edifice.

The first style, denominated by Mr. Rickman "Early English," commenced with the reign of Richard the First, in 1189, and was superseded by the next in 1307, the end of the reign of Edward the First. It is principally distinguished by long narrow windows, and bold ornaments and mouldings. The window being so essential a mark of the style, claims to be considered in the first place.

The Early English window is invariably long and narrow; its head is generally the lancet, or highly pointed arch, but is sometimes formed by a trefoil. In large buildings there are generally found two or more of these combined, with their dripstones united. Three is the usual number, but sometimes four, five, seven, and in one instance (the east end of Lincoln Cathedral) eight are employed. When combined, there is usually a quatrefoil between the heads, and where there are many, the whole is sometimes covered by a segmental pointed dripstone, to which form the windows are adapted, by the centre one being raised higher than the rest, which are gradually lowered on each side to the extremity. Sometimes, in late buildings, two windows have a pierced quatrefoil between them, and are covered by a simple pointed arch as a dripstone, thus approaching so nearly the next style as not to be easily distinguished from it: this arrangement may be seen in the nave of Westminster Abbey. In large buildings the windows are frequently decorated with slender shafts, which are usually insulated and connected by bands with the wall. A fine example of this may be seen at the Temple Church, London, one of the purest buildings existing of this style.

The circular, rose, or catherine-wheel window is frequently found in large buildings of this style, in which, however, it did not originate, being found in Norman edifices. It appears to have received much attention from the architects of the period, being worked with great care.

The doors of this style are distinguished by their deep recess; columns usually insulated in a deep hollow, and a simple pointed arch, nearly equilateral in the interior mouldings, but in the exterior, from the depth of the door, approaching the semicircle. They are also frequently ornamented by a kind of four-leaved flower placed in a hollow. In large buildings they are often divided by one or more shafts (clustered) in the centre, with one of the circular ornaments above.

To the steeples of this period were added, in many instances, spires, many of which are finely proportioned and form a very characteristic and elegant finish to the buildings they accompany. They have usually ribs at the angles, which are sometimes crocketed; and in some instances they are still farther enriched with bands of quatrefoils round the spire. The towers are usually guarded at the angles by buttresses, but octagonal turrets are sometimes met with, surmounted by pinnacles of the same plan. In small churches the slope of the spire sometimes projects over the wall of the tower, which is finished by a cornice, and the diagonal sides of the spire (generally octagonal) are sloped down to the angles.

The arches of this style are chiefly distinguished by very numerous, though, for their size, bold mouldings, with hollows of corresponding depth: the lancet arch is chiefly used, though many are found much more

obtuse. The form of the arch, indeed, as Mr. Rickman observes, is by no means a certain criterion for the distinction of the styles, each form being met with in buildings of each style, except the four-centered.

The piers are distinguished from those of the other styles by being surrounded with bands, which sometimes are confined to the shafts, and sometimes are continued on the pier. The capitals are usually composed by plain bold mouldings. The plan of these piers is usually a circle, surrounded by small shafts, but a beautiful variation is found in Salisbury Cathedral.

The buttresses of this style are chiefly distinguished by their simplicity, having very few sets-off, and very rarely any ornament in their faces. Frequently, indeed, as at Wells Cathedral (the nave of which is very early in this style), they retain the Norman form, of very broad faces with slight projections, with a shaft inserted in the angles, and are continued no higher than the cornice. The flying buttress was not used till late in this species of architecture.

The ornamental parts of the style now remain to be considered, which, till near its conclusion, were but sparingly used, and those, for the most part, of a very rude description. In the west front of Wells and Peterborough Cathedrals may be seen specimens of the taste of the period in these particulars, which are wholly unworthy of imitation; but in the interior of Salisbury are many details of a later date, which are very elegant, and will bear the most minute examination.

It may be sufficient to mention, that in all the ornamental and minute details during this period, as well as in the more important parts, the boldness and contempt of refinement, which are infallible marks of an early age, are very apparent, for which reason we shall defer the description of many ornamental details (which, nevertheless, were practised, and with success, in the latter part of this period) till the next style, in which they were brought to perfection.

There is, however, one ornament peculiar to this style which it is necessary to notice before we proceed farther. It resembles a low pyramid, of which the sides are pierced in the form of curvilinear triangles, bending inwards, and is usually placed upon a hollow moulding, from which it is sometimes entirely detached except the angles. It has yet received no regular appellation, on account of its being so unlike any other object as to be with difficulty described, or even delineated, and we believe it must be seen to be accurately comprehended. The only attempt at designation it has received is, the *toothed ornament*. The reason for applying such a name to it we leave for the ingenuity of the reader to discover.

The Early English style of Gothic architecture may, we think, without impropriety, be compared to the Doric order of the Greeks. Like that, it is the first attempt of a people emerging from barbarism, and like that, it possesses all those qualities which it is natural to expect from such a state of society. Strength and simplicity are its predominating characteristics: ornament, except the most bold and artless, is foreign to its nature, and can never be introduced with propriety. For this reason it may be employed with great advantage in churches, where expense is an object, as a finer effect may be produced by the use of this style than of any other whatever, at an equal cost. Of the fitness of Gothic architecture for ecclesiastical edifices, we presume it is now needless to say much. The circumstances of its having had its origin in Christian worship, and consequent adaptation to its ceremonies, its fitness for the climate, and its devotional effect upon people in general, seem to point it out as peculiarly appropriate for this service. In exterior effect Gothic architecture is very defective, and never more so than in this style. We have, indeed, scarcely one front which is at all reconcileable to good taste. That of Salisbury Cathedral is generally admired, but we can see no reason for the preference. A consciousness of this defect of the style led the architect of that of Peterborough Cathedral to make use of a singular expedient. Three ponderous arches supported by triangular piers receive the weight of three gables, and at each lateral extremity is a square turret, containing a staircase, and surmounted by a spire, one of which has been already described. The effect of the composition is grand, but it is not worthy of imitation. A field is thus offered for the exercise of modern invention, which, as this kind of architecture becomes better understood, it is to be hoped will not be neglected: much has been done, but something, we conceive, remains to do, to render it a worthy and formidable competitor with the long practised and deeply studied architecture of Greece and Rome.

The style next in order to the Early English is denominated, by Mr. Rickman, *Decorated English*, as possessing a greater degree of delicacy than the former, without the excessive detail of the style which succeeded it. It ceased to be used soon after the death of Edward the Third, which happened in 1307. Its prominent feature is also found in its windows, with which, therefore, we shall commence our description.

The windows of this style are distinguished from those of the last by being larger, and divided into lights by slender upright stones, called mullions.

Of decorated windows there are two descriptions. 1. Where the mullions branch out into geometrical figures, and are all of equal size and shape; and 2. Where they are dispersed through the head in curves of various descriptions (which is called flowing tracery) and are usually in windows of more than three lights, of different size and shape, the principal mullions forming simple figures, subdivided by the inferior ones. Sometimes the principal mullions are faced by slender shafts, with bases and capitals. The first description is considered the oldest; the principal example which contains these kind of windows is Exeter Cathedral, where they are very large, and nearly all composed of this kind of tracery. Plate 4, fig. 1. The architraves are commonly enriched by mouldings, which sometimes assume the form of columns, and the windows in composition frequently reach from pier to pier. The form of the arch is seldom more acute than that described on the equilateral triangle, and it is generally more obtuse. The richness of these windows invariably depends upon their size, the distance between the mullions being nearly the same in all: the largest, however, do not consist of more than nine lights. The dripstone is in this style improved into an elegant canopy, the form of which is sometimes pedimental, and sometimes an ogee arch: it is decorated with crockets and a finial, and the space inclosed by it and the exterior contour of the arch is sometimes filled with tracery. The great

west window of York Cathedral, one of the finest in the kingdom, has a triangular one. Plate 4, fig. 2.

The circular window was also brought to perfection in this style. A fine example in form, though not in detail, is now the only remains of the ancient palace of the Bishops of Winchester, in Bankside, Southwark. This is of the geometrical description; one of the finest of flowing tracery is in the south transept of Lincoln Cathedral.

The doors of this style are not so distinct as the windows, from those of the former period: double doors are not so frequent, and the shafts are not detached from the mouldings as in the Early English. In small doors there is frequently no column, but the mouldings of the arch are carried down the sides without interruption: there is frequently no base-moulding, but a plain sloped face to receive the architrave. They are surmounted by the same sort of canopies as the windows.

The steeples of this period are distinguished from those of the last in little more than their windows, and a few unimportant details. The north-west spire of Peterborough Cathedral, before described, decidedly belongs to it, though the tower beneath is Early English. The tower and spire of Newark Church, Lincolnshire, are pointed out by Mr. Rickman as a peculiarly fine example.

Of arches little can be said. Of their form, it may be sufficient to observe, that the lancet arch is rarely met with; the Tudor never but in one instance, the nave of Winchester Cathedral, built, or rather cased, by the celebrated William of Wyckham, and it is here necessarily adopted on account of the form of the Norman arch it was employed to conceal. The mouldings are in general less numerous, and consequently bolder than those of the preceding style. In small works the ogee arch is frequently found, and decorated with crockets, and a finial.

The piers of this style are, for the most part, square in their general form, and placed diagonally. The shafts are sometimes filletted, that is, a square narrow face is continued vertically along its surface, projecting slightly from it. The capitals are frequently enriched with foliage, and the bases, in many instances, consist of reversed ogees, with square faces of various projections, and sometimes other mouldings.

Decorated English buttresses are distinguished from those of the last style which are most applicable to it, only by their greater richness in buildings where decoration is not spared, and consequently, in others they are perhaps the least characteristic parts of the composition. They are, however, usually finished by pinnacles, which are generally distinguishable from those of the former style. The flying buttress is almost invariably used, and is also surmounted by a pinnacle, which usually corresponds with the lower one. The buttresses of the aisles of Exeter Cathedral are remarkable for being detached from the wall, the only support they afford to which, is by the arches which connect them with it at the top.

The parapets of this style are sometimes horizontal, and sometimes embattled, each of which are frequently pierced in the form of cinquefoil headed arches, quatrefoils, and triangles. Sunk panels are, however, more common. When plain embattled parapets are employed, the crowning moulding is usually continued horizontally only, the face towards the opening being merely a vertical section.

As many of the ornamental parts of Gothic architecture were brought to perfection during this period, they cannot be better introduced than in this place. Among these the use of crockets is a prominent feature: these are small bunches of foliage running up the side of the *gablet*, afterwards improved into the ogee canopy over doors, windows, and ornamental arches, and finished by a combination of two or more, called a *finial*, which is separated from the rest by a small moulding. They are also used to decorate the angles of pinnacles. Another peculiarity of Gothic architecture is the *feathering* of windows, screen-work, ornamental arches, panels, and sometimes doors. It is called trefoil, quatrefoil, or cinquefoil, according to the number of segments of circles (which are called *cusps*) of which it is composed. A very beautiful door thus ornamented, still exists in St. Stephen's Chapel, Westminster, now the House of Commons.

Although the grotesque is the prevailing character of the sculpture employed in the decoration of Gothic architecture, many small ornaments are found, particularly in this style, designed with taste and executed with the utmost delicacy. They are copied from the beautiful though humble flowers of the field, and are in many instances local.

We have compared the former style to the Doric of the Greeks, and the present may with little less propriety be likened to the Ionic of the same people. Boldness with simplicity characterize the first; elegance and delicacy the second. In both Greek and Gothic orders, ornament to profusion is allowable; yet in neither does it interfere with the composition, and may be entirely omitted. From this circumstance arises an universal applicability, belonging only to the far-famed "*happy medium,*" so often talked of, so seldom attained. In grandeur of composition, simplicity of arrangement, elegance of form, and *perfection* of capability, this style is therefore unrivalled, and may be used with advantage for every purpose of civil architecture. It is, however, perhaps, peculiarly adapted for all churches whose size and situation render them of importance; and in such large buildings where Gothic architecture may be thought desirable, as are of sufficient consequence to allow the architect to think of delicacy in the design of his details.

The last of the three grand divisions of Gothic architecture is the *Perpendicular* Style, commencing in the end of the second, and finally overwhelmed by its own superfluity of decoration and uncompromising minuteness. It was not wholly lost sight of before the reign of James the First, when few buildings were erected without a mixture of Italian work.

The Perpendicular Style, like the others, is most readily distinguished by its windows (whence it also derives its appellation); the mullions of which, instead of being finished in flowing lines, or geometrical figures, are carried perpendicularly into the head. They are further distinguished by a *transom* or cross mullion, to break the height, under which is usually a feathered arch, and sometimes it is ornamented above by small battlements. The architraves of windows in this style have seldom shafts or mouldings as in the former, but are worked plain, and frequently with a large hollow. Although these windows do not admit of any great variety in the disposition of the tracery, they are far more numerous than those of either of the other styles; few specimens of which remain, that do not bear marks of

the rage for alteration which appears to have prevailed at this period.

The *doors* of this style are remarkably varied from those of the preceding ones, by the arch being finished by a horizontal moulding, which is continued down to the springing of the arch, and then shortly returned. This is called a *label:* the space enclosed by it, and the exterior line of the arch is called the *spandrel*, which is commonly filled with a circle enclosing a quatrefoil or other circular ornament.

The *steeples* of this style are for the most part extremely rich: spires are seldom met with, but lanterns are frequently used. A lantern is a turret placed above a building, and pierced with windows so as to admit light into the space below. This is sometimes placed on the top of a tower, as at Boston, and supported with flying buttresses springing from it, and sometimes constitutes the tower itself, as at York, Peterborough, and Ely Cathedrals, where it is placed at the intersection of the cross, and has a very fine effect. The exterior angles are frequently concealed by octagonal turrets containing staircases, but usually strengthened by buttresses either double or diagonal. A most beautiful finish for a steeple is found in that of the church of Newcastle-upon-Tyne, where a small square tower (each side of which is nearly occupied by a window), surmounted by a spire, is wholly supported by arch buttresses springing from the pinnacles of the great tower.

Groining, in perpendicular work, assumes a new and more delicate character. A number of small ribs diverging from a centre, are carried up in the form of one side of a pointed arch, and terminated equidistantly from that centre by a semicircle. As they recede from the point, they are divided by smaller ribs or mullions, and those again subdivided (according to the size of the roof) so as to make all the panels of nearly equal size. These panels are ornamented with feathered arches, &c. in the same manner as the windows, in conformity to which the whole is designed. The intervals between these semicircles are filled with tracery of the same description. This kind of roof is called *fan tracery:* it is exquisitely beautiful, and almost the only kind of groining used in this style. Another description of roof must now be mentioned, of very different character; this is the timber roof, of which Westminster Hall presents so magnificent an example. Plate 4, fig. 3. Here the actual timbers of the roofs are so arranged as to form an architectural combination of great beauty: a wooden arch springs from each side of the building, supporting a pointed central one, finished downwards with pendants: the rest of the framing is filled with pierced panelling. This kind of roof is not found in churches, but it seems well adapted for large halls, appropriated to public business, or any place intended for the occasional reception of large meetings.

The *piers* are remarkable for their depth in proportion to their width: frequently there is a flat face of considerable breadth in the inside of the arch, and a shaft in front running up to support the groining. The capitals, when there are any, are generally composed with plain mouldings, but there is sometimes a four-leaved square flower placed in the hollow.

The *buttresses* and *pinnacles* contain little remarkable, and are only distinguished from those of the last style by their extraneous ornaments, if they have any: the buttresses are sometimes panelled, and in some very late specimens the pinnacles are in the form of domes, of which the contour is an ogee arch.

The *parapets* of this style are generally embattled and pierced; they are worked with great delicacy in the form of quatrefoil circles, &c.

Having in the preceding pages briefly detailed the various Styles, we may now furnish a few examples of their application in various edifices. The first of these is represented in Plate 2, Fig. 1, Fine Arts, forming the porch of Redcliffe Church, Bristol. The exact date of this part of the edifice is not known, but the external arch is very similar to one in the Church of Batalha, which was erected in the fourteenth century. It affords a very rare and beautiful example of the combination of the pointed arch with the morisco doorway.

The interior, fig 2, which forms our other example, is copied from King's College Chapel, Cambridge, and in point of elegant enrichment it has long been the admiration of all Europe. We have here at one view the whole system of clustered columns and groined roofing, which has served to render this style of architecture so peculiarly fitted for large and solemn edifices. The first stone of this edifice was laid in 1441.

Plate 3, fig. 1, represents the magnificent architecture of Egypt; fig. 2 of the same plate represents the front view and elevation of a Doric temple; fig. 3, that of an Ionic temple; and in fig. 4, the general effect of the Roman or Composite order is given, the other plates giving the details, are referred to in the body of the article.

ARCHITRAVE, in *Architecture*, the lower division of an entablature, or that part which rests immediately on the column. In all the ancient examples of the Doric order still existing in Greece, such as those at Athens and Corinth, and also those at Pæstum, and in Sicily, it has only one facia, and is of great height, being nearly equal to the diameter of the column. In the Doric order of the theatre of Marcellus at Rome, it has only one facia, but is much lower, being only equal to half a diameter of the column. The moderns, such as Vignola, Scamozzi, &c. have generally confined it to this proportion nearly, but have divided it into two facias, taking the idea from some ancient examples of the Doric order in Italy. This term is sometimes, though erroneously, applied to doors and windows.

ARCHIVAULT, the contour of an arch, or a frame set off with mouldings running upon the faces of the arch-stones, and bearing upon the imposts.

ARCTATIO, a constipation of the intestines from inflammation, or a preternatural straightness of the pudendum muliebre.

ARCTIC, in *Astronomy*, an epithet given to the north pole, or the pole raised above our horizon. It is called the arctic pole, from the constellation of the Little Bear, nearly pointing out the north pole.

The arctic circle is a lesser circle of the sphere, parallel to the equator, passing through the north pole of the ecliptic, and 23° 28′ distant from the north pole, from whence its name. This and its opposite, the antarctic, are called the two polar circles; and may be conceived to be described by the motion of the poles of the ecliptic, round the poles of the equator, or of the world. The arctic circle is the boundary of the north frigid zone.

ARCTOPHYLAX, in *Astronomy*, the Bear-Ward, a name for Boötes.

ARCTURUS, in *Astronomy*, a fixed star of the first magnitude, in the constellation of Arctophylax, or

Boötes. This star was known to the ancients, and is mentioned by Job, and also by Virgil.

ARCTUS, in *Astronomy*, a name given by the Greeks to two constellations of the northern hemisphere; by the Latins called ursa major and minor; and by us the greater and lesser bear.

ARCUATIO; a gibbosity of the fore parts, with a curvation of the bone of the sternum of the tibia, or dorsal vertebræ.

ARCUBALISTA. See BALISTA.

ARDASSES; a peculiar coarse kind of silk used in Persia.

ARDASSINES; the unwoven silk known under this name affords a striking contrast to that alluded to in the previous article. It is the finest used in the looms of France.

ARDOR VENTRICULA; a disease of the stomach, better known as *heart-burn*.

AREA, in *Geometry*, the superficial contents of any figure, as a triangle, quadrangle, &c., which is estimated by small squares, or parts of squares.

AREA, in *Architecture*, strictly a dry place, but more generally applied to the open space at the bottom of a house.

ARENA, an obsolete term for gravel in the human body.

ARENA, in *Architecture*, the whole internal plan of a temple.

AREOLA; the coloured circle round the breast.

ARES, an alchemical term descriptive of the great first cause.

ARGAL; crude tartar in the state in which it is taken out of empty wine-vessels.

ARGAND LAMP. See LAMP.

ARGEMA; a disease of the eye.

ARGENT, in *Heraldry*, a term used to denote the white colour of a shield, and in several terms of art employed by the goldsmiths to denote silver.

ARGENTUM ALBUM; a term anciently employed for silver money.

ARGENTUM MOSAICUM; an amalgam of tin, bismuth, and mercury, employed for colouring plaster of Paris.

ARGETENÂR; a star of the fourth magnitude in the constellation Eridamus.

ARGILLACEOUS; white pure earth. The argillaceous earths generally are the basis of earthenwares.

ARGO; a constellation in the southern hemisphere.

ARGUMENT, in *Astronomy*, any quantity or equation on which depends another quantity relating to the motion of the planets; or, in other words, it is an arc whereby another arc is to be sought, bearing a certain proportion to the first arc. The argument is of different kinds, namely—argument of inclination, or argument of latitude, the arc of a planet's orbit, intercepted between the ascending node and the place of the planet from the sun, numbered according to the succession of the signs. Menstrual argument of latitude is the distance of the moon's true place from the sun's true place, by which is found the quantity of the real obscuration in eclipses. Annual argument of the moon's apogee, the distance of the sun's place from the moon's apogee, that is, an arc of the ecliptic, comprised between these two places. Argument of the parallax, denotes the effect it produces on the observation, which serves for determining the true quantity of the horizontal parallax.

ARGYROPEA. The art of making silver by the alchemists.

ARIDED; a fixed star of the second magnitude in the Swan's Tail.

ARIDURA, in *Medicine*, a term employed to describe a general wasting of the body.

ARIES; one of the twelve signs of the zodiac. It is usually termed the vernal sign.

ARIES; the original name for the battering-ram. In tracing the progress of invention, it is curious to observe how much more rapidly the destructive arts advance than those which are intended for the benefit and real advantage of mankind. The hurling of a stone by manual strength was speedily succeeded by the sling, balista, and aries; and in the same way we find in the very infancy of the arts the Greek fire taking the place of simple bitumen, and that again superseded by gunpowder, which appears likely to be superseded by the transatlantic invention of high-pressure steam.

The aries, as an instrument for battering walls, is said to have been invented by Artemanes of Calzomene, a Greek architect who flourished 441 B. C. The machine is thus described by Josephus: "It is a vast beam, like the mast of a ship, strengthened at one end with a head of iron, something resembling that of a ram, whence it took its name. This was sometimes supported by men, and at other times hung by the middle with ropes to another beam, which lay across two posts; and hanging thus equally balanced, it was by a great number of men drawn backwards and pushed forwards, striking the wall with its iron head. But this engine did most execution when it was mounted on wheels, which is said to have been first done at the siege of Byzantium under Philip of Macedon." Plutarch informs us, that Marc Antony in the Parthian war made use of a ram fourscore feet long; and Vitruvius says, that they were sometimes 106 and sometimes 120 feet in length; and to this much of the force and strength of the engine was in a great measure owing. The ram was managed at one time by a whole century of soldiers; and they being spent were replaced by another century, so that it operated continually.

In the graphic delineation beneath, the *aries* is seen in operation in the foreground, supported on the shoulders of seven soldiers, and the men having given momentum to the ram by retreating a few steps, are supposed to be advancing to the attack and striking the stones with the whole weight of their bodies acting in unison with the ram head. It may be proper to observe, that the aries owed all its force to its being driven perpendicular to the surface of the stone.

We allude to this, as the artist has by a slight

misconception made it strike obliquely. At the back of this stirring scene a similar beam suspended by a chain is made to operate by piercing the wall with a pointed iron head.

Arish; a Persian measure of length containing about thirty-eight inches.

Arista, in *Astronomy*, an obsolete term for the spica virginis.

Arithmetic, the science whose object it is to investigate the relations and properties of numbers.

Of the origin and early progress of arithmetic we know nothing; the remotest source to which we can trace it is Egypt, whence it is said to have been brought to Greece by Thales the Milesian, about 600 years before Christ. The oldest treatise on the subject is that written by Euclid, the celebrated Greek geometer, and is contained in the seventh, eighth, and ninth books of his Elements.

The Greeks, in counting numbers, reckoned as we do by periods of ten; this we perceive, from the structure of the words of their language, used to signify numbers greater than ten. Thus the term for *eleven*, is a compound of *one* and *ten*; for *twelve*, of *two* and *ten*; and *thirteen*, *fourteen*, &c. up to *twenty*, are literally expressed by *three* and *ten*, *four* and *ten*; and so on. But though, in reckoning, the Greeks divided numbers into the same periods as we do, their method of representing them in a written form more concise than that of ordinary language, was totally different from ours. They were, it is well known, ignorant of our system of decimal notation, which may indeed be termed one of the simplest and most perfect of human inventions, as it enables us to represent any number, however great, by means of only ten characters.

The earlier marks employed to represent numerals were, of necessity, suited to the nature of the materials on which they were inscribed, and the quality of the instruments employed to trace them. In carving on pillars of stone, none but straight lines are capable of being cut with facility, and this remark applies still stronger to materials of wood. Hence the primary numeral characters, like the early forms of the letters of the alphabet, which are preserved with little variation in the capitals which we employ, were wholly of this nature. When this method was brought to some degree of perfection, the uniform broad strokes were dismissed, and the letters of the alphabet which most resembled their several combinations were adopted in place of them. But when the Greek alphabet was extended and improved by the introduction of the small characters, these were sometimes employed in their natural succession to signify the lower ordinal numbers, an arrangement which we observe in the heading of the books of the Iliad and Odyssey. The first letter, α, was the figure which they used to represent *one*; the second, β, denoted *two*; the third, γ, *three*, and so on, up to ω, or *twenty-four*, which was necessarily the limit of this notation. A second method consisted in the adoption of the initial letters of the words expressing certain numbers as representations of those numbers. Thus the Π of ΠΕΝΤΕ stood for *five*, the Δ of ΔΕΚΑ for *ten*, the H, which is the first letter of the aspirated ʽΕΚΑΤΟΝ, for an *hundred*, the X of ΧΙΛΙΑ for a *thousand*, and the M of ΜΥΡΙΑ for *ten thousand*. In order to extend this notation, a simple and ingenious device was resorted to; a large Π placed over or around any letter augmented its value five thousand times; thus |Δ|, denoted fifty thousand, and |H| five hundred thousand.

But a mighty improvement was afterwards effected by the Greeks in their arithmetical notation. The twenty-four letters of the alphabet were distributed into three classes, corresponding to units, tens, and hundreds; and to complete the characters for the nine digits, three additional marks were introduced. Thus the first eight letters with an additional character, represented the units; the next eight with an additional character, represented the tens; and the remaining eight with another additional character, the hundreds. This arrangement of the symbols it is obvious could extend only to the expression of the number nine hundred and ninety-nine; but by writing an *iota* under any letter, the value of it was augmented a thousand times. And by subscribing the letter M, the initial letter of the word signifying a *myriad* or ten thousand. A still further advance was made, and the power of the letters increased ten thousand fold. This latter object was sometimes more simply attained by placing two dots over the character, whose value was to be augmented.

Such is briefly the very beautiful and ingenious system of numeration which prevailed amongst the Greeks. It was on the whole remarkably compact, and, as an instrument of calculation, might be deemed sufficient for every practical purpose; but to fulfil the objects of science something more was necessary. The penetraating genius of Archimedes quickly suppiled the desideratum. In a curious tract, entitled *Arenarius*, this philosopher amused himself with showing, that it was possible, assuming the estimation of Aristarchus of Samos, and other astronomers of that age, to represent the number of particles of sand which would be required to fill the sphere of the universe. He took the limit of the ordinary numeral system, or ten thousand times ten thousand, that is, an hundred millions, as the root of a new scale of progression, which therefore advanced eight times faster than the simple decimal notation. Successive periods, which he termed *octads*, were thus formed rising above each other by the continued multiplication of an hundred millions. Archimedes proposed to carry this comprehensive system as far as eight periods, which would therefore correspond to a number expressed in our mode by sixty-four digits. From the nature of a geometrical progression, he demonstrated that proportional numbers would range at equal distances; and, consequently, that the product of any two numbers must have its place determined by the sum of the separate ranks, a principle which involves the theory of logarithms.

The fine speculation of the Sicilian philosopher does not, however, appear to have been carried into effect; and without actually performing those calculations, he contents himself with merely pointing out the process, and stating the approximate results. But Apollonius, the most ingenious and inventive, next to Archimedes, of all the ancient mathematicians, resumed that scheme of numeration, simplified the construction of the scale, and reduced it to a commodious practice. For greater convenience, he preferred the simple myriad as the root of the system, which, therefore, proceeded by successive periods, corresponding to four of our digits, and distinguished by breaks or blanks.

But the Greek notation was not adapted for the

descending scale. To express fractions, two distinct methods were followed; if the numerator were unity, the fraction was indicated by accenting the denominator; in other cases, the denominator was written a little above to the right hand of the numerator. The laborious operations required for the management of complex fractions gave rise to the sexagesimal arithmetic, the introduction of which, about the year 130, is commonly ascribed to Ptolemy. In this notation, which was suggested by the astronomical division of the circle, the integral numbers from one to 59, were expressed in the ordinary manner; 60 was called a *sexagesima prima*, and was denoted by unity with an accent placed over it; 120, or twice 60, was represented by *two*, accented; 240, or four times 60, by *four* accented, and so on till 3,600, or 60 times 60, which was called *sexagesima secunda*, and expressed by unity with two accents. Then 60 times 3,600, or 60 multiplied by itself twice, was represented by unity with three accents, and so on. If the number to be represented were not an exact multiple of 60, the portion of it which was the greatest multiple was written with its proper number of accents, and the excess was joined to it without any; thus 3,614 would have been expressed by writing the character for *one* with two accents, and annexing the number 14 written in the ordinary manner. The operations with sexagesimal fractions were performed in the descending scale on a principle quite similar to that which Archimedes had before laid down. Each period of the multiplier was multiplied into a period of the multiplicand, and this product was then thrown to a rank depressed as much as the conjoined descents of the two factors.

We have thus very briefly noticed the method of notation which was adopted by the Greeks; for a fuller account of that, and the systems employed by other nations, we must refer to the article NUMERALS. We may here however observe, that the great and radical defect of the Greek system consisted in the want of a general mark analogous to our cypher, and which without having any value itself, should serve to ascertain the rank or power of the other characters by filling up the vacant places in the scale of numeration. Had Apollonius classed the numerals by triads instead of tetrads, he would have greatly simplified the arrangement, and avoided the confusion arising from the admixture of the punctuated letters which were used to express thousands. The extent of the alphabet was favourable to the first attempts to represent numbers by symbols; since, with the addition of three intercalations, it furnished characters for the whole range below a thousand; but that very circumstance in the end proved a bar to future improvements. It would have been a most important stride to have next exchanged those triads into monads, by discarding the letters expressive of tens and hundreds, and retaining only the first class, which with its inserted character should denote the nine digits. The *iota*, which signified ten, now losing its force, might have been employed as a convenient substitute for the cypher. By such progressive changes, the arithmetical notation of the Greeks would at last have reached its utmost perfection, and have exactly resembled our own. A wide interval no doubt did still remain; yet the genius of that acute people, had it continued unfettered, would in time, we may presume, have triumphantly passed the intervening boundaries.

Our modern system of notation we unquestionably derived from the Arabians, who had themselves obtained this invaluable acquisition from their extended communication with the east. It seems to be pretty generally determined that the mode of expressing any number, however great, by means of nine significant characters, and a blank one employed to keep the others in their places, was known in Hindoostan as early as the sixth century, whence it was introduced into Arabia about the middle of the thirteenth, though some would refer it to an earlier date. The period of the introduction of these digits into Europe is a question which has occasioned much discussion. By some it is dated so early as the beginning of the eleventh century, while others are disposed to place it two hundred and fifty years later. As they were doubtless first used by astronomers, and afterwards circulated in the almanacks over Europe, Kircher with some air of probability would refer their introduction to the astronomical tables published by the celebrated Alphonso, king of Castile, in 1252. But it is suspected that in the original work the numbers were expressed in Roman or Saxon numerals, especially as two letters from the same monarch to Edward the First of England, which are preserved in the Tower of London, have the dates 1272, and 1278, still denoted by those ancient characters. One of the oldest authentic dates in the Arabic figures is that of the year 1375, which appears in the handwriting of Petrarch, on a copy of St. Augustine which had been in his possession. Although at that period the use of these characters was still confined to men of learning, it had already begun to spread in Europe.

We have said, that our mode of notation by nine significant characters and a blank one, was known as early as the sixth century in Hindoostan. There is little doubt but that the Chinese were acquainted with the system many centuries earlier; and it is remarkable, that while all the European nations have stopped at the ninth digit, the Chinese from the earliest antiquity have proceeded direct from one to ten, without the use of the zero or cypher, and employing no combination as the Europeans do. From ten they proceed thus:—ten and one, ten and two, ten and three, &c. Twenty is expressed by two and ten; twenty-one, by two ten and one, &c. They have characters expressive of hundred, thousand, and ten-thousand: hence, two hundred, two thousand, or two ten-thousand, would have the numeral *two* preceding it, or in their mode of placing the figures, *over* it, as they read from the top to the bottom of the page.

The first work on arithmetic, printed in England, is that of Cuthbert Tonstall, bishop of Durham. It is entitled *De Arte Supputandi libri quatuor*, and issued from the press of Pynson, in 1522. A copy upon vellum, supposed to have been Tonstall's own, and possessing his autograph, is preserved in the library of Corpus Christi College, Oxford. In 1585 appeared *La Pratique d'Arithmétique*, by Simon Stevin; to which was attached a treatise, entitled *La Disme*, in which decimal fractions were for the first time considered. Previous however to this publication, Peter Ramus had used decimal periods in performing the extraction of the square root of fractions; and according to Dr. Wallis, our countrymen Buckley and Recorde, had employed a similar method for the same purpose as early as 1550. But Stevin was undoubtedly the first author who professedly wrote on

this subject; his work was subsequently translated into English in 1608. The theory and notation of decimals were afterwards greatly improved by Baron Napier, in his *Rhabdologia*, and arithmetic was brought to its present state by the discovery of continued fractions, which was made by Lord Brounker in 1670, and which enabled him to approximate very near to the ratio of the circumference of the circle to its diameter.

NUMERATION.

The first elements of arithmetic are acquired by us during our infancy. A knowledge of our present mode of reckoning and writing numbers is attained at so early an age that we hardly recollect how we began. As soon as we are able to exercise our reasoning faculties, we find ourselves in the habit of counting by tens, and so simple and natural does the method appear, that without reflecting on the means formerly practised by nearly all the world, and still in use among savages for effecting the same object, we are induced to conclude that it arises from something inherent in the nature of numbers, and that we acquired it simultaneously with our ideas of them. But a little consideration will enable us to see the impropriety of such a conclusion.

The idea of numbers having been acquired, it is natural to suppose that our notions of those which most frequently present themselves should be more clear than of any others. The perpetual occurrence of objects singly and grouped in pairs, must render the ideas of *one* and *two* familiar to us; while of numbers, such as those which we express by the terms *twenty-three* and *twenty-four*, we cannot have any distinct apprehension. Hence, if we wished to convey an idea of them, we could only do so by saying that they bear a certain relation to the simpler ones.

The classification by pairs, which nature points out, would suggest the simplest mode of reckoning. Hence the dual, though also retained by the Greeks, occurs in the languages of all barbarous tribes. Counting these pairs again by twos and repeating the same process, we arrive by progressive steps at the numbers *four*, *eight*, and *sixteen*, &c., to which the other numbers are easily reducible. Thus *thirteen* being composed of *eight*, *four*, and *one*, would according to such a system of numeration be called "quadruple pair, double pair and one," or denominated more concisely by words of corresponding import. This plan of arrangement, termed the binary scale, seems at a certain period of society to have prevailed in most countries; and Leibnitz has extolled the system with abundant extravagance. It would no doubt from its naked simplicity supersede the application of thought, and reduce all the operations which occur in arithmetic to the mere labour of writing; but nothing would thus be gained in practice, since advancing with excessive slowness, it would soon require a multiplicity of words, and a fatiguing complication of characters.

The next step in the progress of numeration was probably to assume the double pair, or four, as the root of the scale. The ancient Mexicans appear to have reckoned by fours, and to have afterwards advanced in their numeration by combining the products of four with those of ten.

But nature has furnished the universal standard of computation in the fingers of the hand, the practice of counting by which must have been so familiar in the earlier periods of society. All nations accordingly have reckoned by *fives*, and after the fingers of one hand had been counted over, it was a second, and perhaps a distant step, to proceed to those of the other. The primitive words expressing numbers probably exceeded not five. To denote, *six*, *seven*, *eight*, and *nine*, the North American Indians repeat the *five*, with the successive addition of *one*, *two*, *three*, and *four*. Could we safely trace the descent and affinity of the abbreviated terms denoting the numbers from five to ten, it seems highly probable that we should discover a similar process to have taken place in the formation of those terms in the most refined languages; the structure of those denoting numbers above ten, sufficiently betrays the influence of the arrangement by that number in their formation.

The process of reckoning with the fingers of both hands having become general, we may conceive our present system of numeration to have been formed thus:—A man has to count a number; to accomplish this he makes use of his fingers, and for every *one* that he counts he lays down a finger on the table: when he has advanced to ten he has reckoned all his fingers, and can continue no further. Therefore if the number which he has to count be greater than ten, he must begin and reckon them over again; but before he can do so, it is necessary for him to mark in some manner that he has already reckoned them *once*, which he might otherwise forget. He does this, we suppose, by making another person put down *one* finger, and then proceeds himself to reckon all his own fingers a second time, when he will have counted a second ten. His companion immediately puts down another of his fingers, to denote that the other has once more reckoned the whole of his. This operation having been continued until the first person has reckoned all his fingers ten times, the second one will then have lain down ten fingers, and will be unable to proceed further. It becomes therefore necessary to employ a third person, who shall do for the second what the second does for the first; that is, mark by laying down *one* of his own fingers that the other has lain down *all* his. The second will thus be at liberty to recommence his registering of the operations of the first, and will be enabled to continue until he has again put down all his fingers, when he must stop until relieved by the third marking that he has done so, by laying down another of his. This operation is continued until the first person finds that the whole number is counted; he then perceives that he has got, say *seven* fingers down, that the second has *three*, and the third *eight*. Now as the first lays down a finger for every *one* that he counts, the seven fingers which he has down show that he has counted *seven ones*. But every finger which the second puts down denotes, not that he has counted one, but that the first has counted ten, which, being unable to mark them with his own fingers, he has employed those of the second to mark; therefore the three fingers which the second has down represent ten counted three times, or *three tens*. The third puts down one of his fingers every time that the second puts down all of his; but every finger which the second puts down represents a *ten*, therefore every one of the third must represent a ten of tens; and the eight fingers which he has down denote that a ten of tens has been reckoned eight times. Hence the

whole number which has been counted is seven ones, three tens, and eight tens of tens.

Such we may conceive to have been the original formation of our decimal scale of arithmetic, traces of which we may discern in the structure of language. If the primary import and composition of δεκα, ἑκατον, χιλια, and μυρια, the Greek terms for a *ten*, a *hundred*, a *thousand*, and a *ten thousand*, could be safely ascertained, we should doubtless discover the influence of the denary system in their formation. It is strongly marked in the composition of the names of all of the numbers between ten and twenty. But the origin of the names imposed on the radical numbers appears most conspicuously displayed in the nakedness of the savage dialects. The Muysca Indians, who formerly occupied the high plain of Bogota, in the province of Grenada, were accustomed to reckon first as far as ten, which they called *quihicha*, or a *foot*, meaning no doubt the number of toes on both feet, with which they commonly went bare and exposed; beyond this number, they used terms equivalent to *foot one*, *foot two*, &c., corresponding to *twelve*, *thirteen*, &c. Another tribe, which likewise inhabits South America, the Sabiconos, call *ten*, the root of the scale, *tunca*, and repeat only the same word to signify a *hundred* and a *thousand*; the former being termed *tunca-tunca*, and the latter *tunca-tunca-tunca*. Our own dialect, as immediately derived from its Gothic stem, betrays a composition not less rude or expressive than the simple articulation of the Sabiconos. According to the authorities collected by a celebrated German philologist, the late Adelung, the word *eleven* was most anciently written *einlif* or *einlivin*, being compounded of *ein*, or *one*, and the verb *liban*, to *leave*, and therefore signified merely *one, leave;* that is, retain *one*, and set aside, no doubt, *ten;* the root of the scale *twelve* has the same derivation. The names *twenty*, *thirty*, *forty*, &c., have the terminating syllable *ty*, which corresponds to *zig* in German, and *zug* or *zuch* among the oldest writers of that parent tongue. This termination is derived from the verb *ziehen*, to *draw;* and hence *twenty* means simply *two drawings*, *thirty*, *three drawings*, &c., intimating evidently that so many tens are drawn or separated from the heap to be counted. The term *hundred*, which also runs unvaried through all the branches of the Gothic, is formed of *hund*, which anciently signified only *ten*, and *red* or *ret*, a participle from the verb *reitan*, to reckon or place in rows. The compound would therefore intimate as much as *ten times told*. In the Gothic translation of the Gospels, made by Ulphilas in the fourth century, *one hundred* is expressed by *taihund-taihund*, or the word for *ten* merely doubled; exactly like the *tunca-tunca* of the Sabiconos of South America. But in the Anglo-Saxon version, which was made about three centuries later, *one hundred* is denoted by *hund teontig*, meaning *ten of ten drawings*. In the same curious monument of our early language, *hund seafantig*, or *ten of seven drawings*, is employed to express *seventy*. It seems probable that *hund* and *ten*, or *teon*, were only variations of the same word. The term a *thousand* is merely an abbreviation of *diuis-hund*, its earliest form. The prefix *diuis* is the same as the word *twice*, and *hund* was probably contracted for *one hundred;* the combined expression would therefore signify a *redoubled hundred*, or *one hundred repeated ten times*.

To return to our example. The man in question has counted the number which he required; let us suppose that his object in so doing has been to ascertain how many stones are contained in a certain heap. He is now enabled to convey to himself a notion of what the number of the heap is; for he has found that it is composed of seven single stones, three collections of ten stones, and eight other collections, each of which contains ten of those first collections, or eight collections of tens of ten; all numbers which are familiar to him and any one of which he can instantly present to himself by laying down so many fingers. This is not however the exact form of expression we now use: instead of a *ten of tens*, we say a *hundred*, and instead of a *three of tens*, we say *thirty*, and the whole number we should denote by *eight hundred and thirty seven*. But, as we have already observed, the original import of a *hundred* is equivalent to that of a *ten* of *tens*, and of *thirty* to that of a *three of tens*. As numbers were reckoned by tens, separate names were required for only *one*, *two*, *three*, &c.; *ten*, *eleven*, *twelve*, &c. were expressed by a compound which conveyed the notion of *ten* and *one*, *ten* and *two*, &c. But in consequence of the modifications which in the course of time our language has undergone, the structure of the word *eleven* no longer affords us a clue to its meaning. We learn indeed from an examination of the form in which it occurs in our parent tongue, the Gothic, that it originally did so; but to us, in its corrupted state, it has more of the appearance of a name arbitrarily chosen to represent the idea of the number which it expresses, than of a derivative or a compound. If all the words in our language which express numbers, had been preserved in their primitive structure and composition, without the slightest deviation from the form in which they were at first used, our system of numeration would explain itself. It is true that but a little of reflection or examination is even now required in order to render it perfectly clear and simple, but could the necessity of that little be avoided in acquiring the foundation of so elementary a science as arithmetic, a point of material advantage would be gained.

This method of expressing large numbers by means of a few names, is unlimited in its application; were it not so, our language would be imperfect. For numbers are infinite, that is to say, there is no *greatest* number, because however great a number may be, we can always by adding *one* to it obtain a greater; therefore we cannot say that we are able to give names to all numbers, unless we employ either an infinite number of isolated words to represent them, or a few which are susceptible of being combined to an unlimited extent. Of these the first is impossible; the other is the system we have adopted. As we express a *ten of tens* by a *hundred*, so a *ten of tens of tens* or a *ten of hundreds* is denoted by a *thousand;* a *ten of thousands* by a *ten thousand;* a *ten of tens of thousands* by a *hundred thousand;* and a *ten of hundreds of thousands*, or a *thousand of thousands*, by a *million*. This word we borrow from the French language, in which a thousand being denoted by *mille*, a thousand thousand is very regularly expressed by *million*. In like manner, as a thousand thousand is denoted by a *million*, a *thousand thousand thousands*, or a *thousand millions*, is expressed by a *bi-million* contracted into a *billion*, *bi* being the root of the Latin word *bis*, which signifies two. A thousand billions is a trillion, a thousand trillions a quatrillion, a thousand quatrillions a quintillion, and so on to sextillions, septillions, octillions, &c. The formation of these names is very regular;

thus, a *thousand thousand* or a *mille mille*, which is a *mille* redoubled once, is a *million*; a *thousand millions* or a *mille mille mille*, is a *bi-million* or *billion*, meaning a *mille* redoubled twice; a *thousand billions* or a *mille mille mille mille*, which is a *mille* redoubled three times, is a *trillion*, or a compound of *mille* with the root of the Latin word for *three*, and the termination *-ion*. The *quatrillion* is similarly formed, *quatr-* being the root of the Latin word for four; as are also the *quintillion, sextillion, septillion, octillion, nonillion*, &c., which contain respectively the roots of the Latin terms for *five, six, seven, eight, nine*, &c. The general principle observed in the formation of these compounds is this: as the numbers which they represent are the results of the reduplication of a *thousand*, or *mille*, a certain number of times, each of them consists of three parts: the termination *-ion*, which denotes that the operation of reduplication is to be performed; the word *mille* representing the number *on which* it is to be performed; and the prefix of the root of the Latin word which expresses *how many times* it is to be performed.

The inconvenience which, in reasoning upon numbers, would necessarily result from the use of their *names*, written at full length, has given rise to the employment of symbols or *figures*, to represent them in a shorter and more compact manner. It is evident that, as we can express in words all numbers by means of only ten separate *names*, we cannot require *more* than ten separate *symbols* to represent them in figures. But nine, as we shall see, are sufficient, and the characters which are employed for this purpose by almost all civilized nations are,

1, 2, 3, 4, 5, 6, 7, 8, 9,

which represent respectively,

One, two, three, four, five, six, seven, eight, nine.

The number eight hundred and thirty-seven would then be shortly expressed by 8 hundred, 3 tens, and 7.

The question which now occurs is, cannot we shorten this abridged form itself? Suppose that we denote the tens by marking their number with one accent, and the tens of tens, or hundreds, with two accents; the number will then be expressed by 8″3′7. Of course we are not bound to arrange the collections exactly in this order; on the contrary, any one of the following ways will do just as well: 8″73′, 3′8″7, 3′78″, 78″3′, 73′8″. But one certain method is all that we want, and in making a choice it is most natural to prefer an arrangement in which the different collections stand in the order of their magnitude, either the largest or the smallest being placed first, thus, 8″3′7, or 73′8″. Of these, the former is that which is universally adopted.

We now see why a separate charater for ten was unnecessary; it can be easily represented by 1′.

The use of these accents would naturally be extended to numbers beyond hundreds; thus, as we denote a ten by one accent, and a ten of tens, or a hundred, by two accents, in a similar manner we should represent a ten of tens of tens, or a thousand, by three accents, a ten of thousands by four, and so on. But it would soon be observed, that the accents were unnecessary; for as the figure with one accent would always be the second from the right, that with two accents, the third, and so on, it is evident that the place of each figure would determine how many accents were to be written over it. Therefore, if we put the figures in their right places, we may omit their accents; and thus the number 8″3′7 may be written 837.

But there are some numbers of such a nature, that if we arrange the collections of *one, ten*, &c., which compose them in the order of their magnitude, and give each its proper accent, the singly accented figure will not be the second from the right, nor the doubly accented one the third, &c. Thus six hundred and thirty would be expressed by 6″3′, in which 3′ is the first figure from the right instead of being the second, and 6″ the second instead of being the third. Therefore, if, in this case, we omit the accents, the place of each figure will not point out how many belong to it. The reason is plain; the number six hundred and thirty contains an exact number of tens; that is to say, if we were to distribute six hundred and thirty faggots into bundles of ten, there would be no single faggots left. But how are we to obviate the difficulty? What must we do in order to render our method of writing numbers general and uniform? The simplest plan which presents itself is this: as the difficulty arises from the collections getting out of the places appropriated to them, in consequence of its happening that there are no figures in some of the other places, let us bring them back by putting a figure in each of the empty places. But the figure which we employ for this purpose must not be one of those which we have already got, and each of which stands for a number, or we shall alter the value of the number which we want to express; therefore we must invent a new character.

The one which is commonly used is 0, the *cipher*, or *zero*, as it is called; and by subjoining this figure to 6″3′, we shall bring 3′ into the second place, and 6″ into the third. We may now, therefore, omit the accents, for the place of the figures *will* point out how many belong to them; and the number becomes 630. Again, in representing three thousand and four, or 3‴4, 3 ought to be in the fourth place from the right; we must, therefore, insert two blank characters in order to bring it there, or write 3004. Hence, in representing any number by figures, the following arrangement is adopted: write, in the first place, to the right the *ones*, or *units*, as they are also called; in the second place from the right, put the *tens*; in the third, the *hundreds*; in the fourth, the *thousands*; in the fifth, the *tens of thousands*; in the sixth, the *hundreds of thousands*, and so on. If there be no separate figure for any one of these collections, that is to say, if any one of them be absorbed, as it were, in one of the following, write in its place a 0, or cypher. The arrangement is exhibited in the example beneath:

2	6	8	0	7	9	5	0	2	8	3	6	4	0
tens of trillions.	trillions.	hundreds of billions.	tens of billions.	billions.	hundreds of millions.	tens of millions.	millions.	hundreds of thousands.	tens of thousands.	thousands.	hundreds.	tens.	units.

It may be observed, that there is a slight and simple abbreviation in the mode of reading a number of any considerable amount. Thus, in the above example, instead of reading two tens of trillions, six

trillions, eight hundred billions, seven billions, nine hundred millions, five tens of millions, two hundred thousand, eight tens of thousands, three thousand six hundred and forty, we use the words trillions, billions, millions, and thousands only once, and say twenty-six trillions eight hundred and seven billions, nine hundred and fifty millions, two hundred and eighty-three thousand six hundred and forty.

We now proceed to explain the elementary operations of arithmetic.

ADDITION.

When we have several numbers, and wish to ascertain or to express how many units are contained in them all taken together, we do it by *addition*. In considering this operation we shall have frequent occasion to speak of two numbers being added together; for the sake of convenience we shall denote this by means of a symbol. Thus, sometimes instead of saying that 8 *is to be added to* 4, we shall prefix to 8, or the number which is to be added, the sign of addition $+$, called *plus;* and then write it after 4, or the number which it is to be added to; as, $4 + 8$. We shall also make use of another symbol, namely, $=$, which is the sign of equality. Thus, whenever we wish to express that one set of numbers is equal to another, we shall employ $=$ instead of the words, *is equal to;* as, $2 + 2 = 4$, instead of 2 + 2 *is equal to* 4.

We may consider every number as formed by the successive addition of unity to itself. Thus, by adding 1 to 1 we obtain the number 2; by adding another 1 we get 3; or, in other language,

$$1 + 1 = 2$$
$$1 + 1 + 1 = 3$$
$$1 + 1 + 1 + 1 = 4$$
$$1 + 1 + 1 + 1 + 1 = 5$$
$$1 + 1 + 1 + 1 + 1 + 1 = 6,$$

and so on. The operation of addition in the ordinary sense, is only an abbreviation of this one. Instead of our object being to get a number which is only *one* greater than another, it is to find that which is *several ones* greater. Hence, as each step in the natural succession of numbers is 1, it is only necessary in adding two numbers, to count forwards from the one of them as many steps as are signified by the other. Thus, suppose that 5 is to be added to 8; reckoning onwards from 8, we pass through 9, 10, 11, 12, until at the fifth step we come to 13, which is therefore the *sum*, as it is called, of 5 and 8. This simple process may be more conveniently performed by counting with the fingers.

It is impossible, strictly speaking, to add together more than two numbers at a time. If we wish to ascertain the sum of several, we begin with finding the sum of the first and second; to this we add the third, and so on. Suppose that the sum of 8, 5, and 6 is to be ascertained; counting forward five steps from 8 we obtain 13, the sum of 8 and 5; and then ascending six steps from this we reach 19, which is therefore the sum of the three numbers. It is usual in finding the sum of more than two numbers, to perform the several additions mentally, and to note down only the result of the last. The progress of the learner will be greatly facilitated by committing to memory the accompanying table, which contains the sum (procured in this way) of every two numbers less than ten.

Addition Table.

	1	2	3	4	5	6	7	8	9
1	2	3	4	5	6	7	8	9	10
2	3	4	5	6	7	8	9	10	11
3	4	5	6	7	8	9	10	11	12
4	5	6	7	8	9	10	11	12	13
5	6	7	8	9	10	11	12	13	14
6	7	8	9	10	11	12	13	14	15
7	8	9	10	11	12	13	14	15	16
8	9	10	11	12	13	14	15	16	17
9	10	11	12	13	14	15	16	17	18

The construction and use of this table are very simple; the one number occupies the horizontal row at the top, and the other, the vertical column at the side, and the sum of the two will be found in the square which is common to the two rows headed by them. Thus, below the column headed by 8 in the top row, and in the horizontal range opposite to 5 stands 13, the sum of those numbers. Tables of this nature are seldom to be found but in the more ancient treatises on arithmetic; they are mentioned by Professor Leslie, in his admirable article on Arithmetic in the *Supplement to the Encyclopædia Britannica,* who observes that he thinks they have been very injudiciously omitted in the later systems of education. It is evident that the same benefits may be derived from their use which attend that of the ordinary multiplication table; for the object of both is the same,—to present in a compact form several results of a certain operation with the view to their being easily committed to memory.

The immediate application of the preceding method to numbers at all large is evidently impracticable; we therefore adopt another. Suppose that 27 is to be added to 32; 27 is 2 tens and 7 units, and 32 is 3 tens and 2 units; therefore, their sum must be 2 tens + 3 tens, and 7 units + 2 units, or 5 tens and 9 units, which we write 59. Again, let it be required to find the sum of 349 and 637;

349 = 3 hundreds + 4 tens + 9 units,
637 = 6 hundreds + 3 tens + 7 units.

Therefore,
349 + 637 = 3 hund. + 6 hund. + 4 tens + 3 tens + 9 units + 7 units, = 9 hund. + 7 tens + 16 units.
But 16 units we commonly express by 1 ten and 6 units. Hence,
349 + 637 = 9 hund. + 7 tens + 1 ten + 6 units,
or as 7 tens + 1 ten = 8 tens,
349 + 637 = 9 hund. + 8 ens + 6 units;
which we write 986.

We perceive then, that the addition of numbers greater than ten, consists simply of the repeated addition of numbers less than ten. We add together separately, first the units of each, then the tens, the hundreds, &c., and the several results thus obtained are the units, the tens, the hundreds, &c. of the sum. For further illustration we subjoin another example,

in which four numbers are to be added together. Let it be required to find the sum of 2519, 8540, 308, and 9347; for convenience we arrange the different collections of each sort in the same column.

2519 = 2 thous. + 5 hund. + 1 ten + 9 units,
8540 = 8 thous. + 5 hund. + 4 tens,
308 = 3 hund. + 8 units,
9347 = 9 thous. + 3 hund. + 4 tens + 7 units.

Therefore 2519 + 8540 + 308 + 9347
= 19 thous. + 16 hund. + 9 tens + 24 units
= 20 thous. + 7 hund. + 1 ten + 4 units
= 20714.

Having thus learnt the principle on which we proceed, we may now in practice omit the decomposition of each number into the collections of units, tens, &c. of which it consists. Thus having arranged the numbers in the following form,

2519
8540
308
9347
——
20714
2112

We need only add together the right hand column which contains the units of each of the numbers, and put down the result for the units' figure of the required sum. If however this result be greater than 9, it will be composed of two figures,—a units' figure and a tens' figure; in that case we must write in the sum only the former, and mark down the other on one side, or as we have placed it, beneath the first, in order that being a tens' figure it may be added to the collection of tens. In the present instance the result of the addition of the column of units is 24, or 2 tens and 4 units; we accordingly write down 4 for the units' figure of the sum, and mark the 2 beneath, remembering, however, that it does not stand simply for 2, but for 2 *tens*. There is no necessity for writing 2 *tens*, because it will be disposed of in the very next step we proceed to, which is the addition of the second column, or that containing the tens. The result of this second step is 9 tens; adding however the 2 tens before mentioned, it becomes 11 tens, or 1 hundred and 1 ten; we therefore write down only the 1 ten in the tens' place of the sum, and place beneath it the 1 hundred, which is to be joined to the collection of hundreds. The addition of the third column, that of the hundreds, gives 16, or joining the 1 hundred which we set aside in adding the preceding column, 17 hundreds, or 1 thousand and 7 hundreds. We therefore write 7 in the hundreds' place of the sum, and place beneath it 1, to be added to the thousands. Adding the third column which contains the thousands, and joining this 1 thousand, we obtain 20 thousands, or 2 tens of thousands. This leaves us no figure at all for the thousands' place, we must consequently place our blank character 0, there, in order that the next collection may fall into its right place, and write the 2 tens of thousands beneath. But as there is no collection of ten thousands to which to add it, we place it by itself in the ten thousands' place. The number thus obtained, 20714, is therefore the sum required.

As soon as a little practice is attained, the plan of writing down the numbers to be *carried*, as it is termed, beneath their corresponding figures in the sum may be discontinued; they can easily be retained mentally, as each of them is always to be added to the next column which is operated upon. We thus deduce the ordinary rule for the addition of numbers which are greater than ten: write the numbers to be added under one another, so that the units' digits shall be all in one column, the tens all in another, the hundreds all in another, and so on; add the numbers in the units' column, and write under it the units' digit of the sum, carrying the tens' digit to be added to the next column; cast up the tens' column with this addition, and write under it the units' digit of its sum, carrying the tens' digit to be added to the next column; proceed thus with every column till the last, under which write its whole sum.

SUBTRACTION.

When we have two quantities and we wish to find how many units will be left in one of them after the number of units in the other has been taken away from it, we ascertain this by performing the operation of *subtraction*. Just as we sometimes write the sign + before a number as a short way of expressing that that number is to be added to another, in a similar manner we employ the *sign of subtraction* —, to denote that the number to which it is prefixed is to be subtracted from another. Thus 8 — 5 is 8 *minus* 5, and means that 5 is to be subtracted from 8.

The object of this operation being precisely the reverse of that of addition, it is performed in a directly opposite manner; that is to say, beginning at that one of the two numbers from which the other is to be subtracted, or the *minuend* as it is called, we count *downwards* as many steps as are denoted by that other, which is termed the *subtrahend*. Thus, suppose that 5 is to be subtracted from 8; descending from 8 we pass through 7, 6, 5, 4, till at the fifth step we come to 3, which is therefore the *remainder* or *difference* required. The auxiliary table which we have given for ascertaining the sum of any two numbers less than ten, will evidently serve also to enable us to find their difference. For if 8 joined to 5 make 13, it is equally clear that 8 taken away from 13 must leave 5. The number 18 is the greatest sum in the table; therefore we can by reference to it find the difference between any number less than that, and any other less than 10. Thus, if we wish to find what will be the remainder after 6 has been subtracted from 14, we search in the row opposite to 6 in the left hand column until we find 14; the number 8, at the head of the column in which 14 stands is the remainder required. The reason is obvious.

As in the case of addition, the immediate application to large numbers of the principle of descending from the minuend, the number of steps denoted by the subtrahend, in order to find their difference would be so long and tedious a method as to be quite impracticable; hence a similar substitute is adopted. Thus, suppose that 345 is to be subtracted from 9587:

9587 = 9 thous. + 5 hund. + 8 tens + 7
345 = 3 hund. + 4 tens + 5

Therefore 9587 — 345
= 9 thous. + 5 hund. — 3 hund. + 8 tens — 4 tens + 7 — 5.

But if to 9 thousand we first add 5 hundred and then from it subtract 3 hundred, the effect is the same as if we only added 2 hundred to it. Similarly, if we first add 8 tens to it, and then take away 4 tens, we in effect only add 4 tens, and if we add 7 units and subtract 5, it is the same as if we added only 2 units.

Therefore

$9587 - 345 = 9$ thous. $+ 2$ hund. $+ 4$ tens $+ 2$
$= 9242$

The correctness of the principle on which we have proceeded is obvious; we have not taken the whole subtrahend from the minuend at once; for as we have before observed the numbers being large, that would be impracticable; but we have separated each into its component parts, and subtracted every one of the parts of the subtrahend from the corresponding part in the minuend.

It is of course impossible, from the nature of subtraction, to perform that operation unless the minuend be at least as great as the subtrahend. For instance, we cannot subtract 6 from 4; because it is impossible to take away from 4 more than there is in 4. But even although this condition be complied with, it may happen that one of the component parts into which we divide the subtrahend is greater than the corresponding part in the minuend; in other words, although the minuend have more hundreds in it than the subtrahend, and therefore be the greater number of the two, yet the subtrahend's collection of tens may be greater than that of the minuend. Thus, suppose that 784 is to be subtracted from 958,

$958 = 9$ hund. $+ 5$ tens $+ 8$ (minuend.)
$784 = 7$ hund. $+ 8$ tens $+ 4$ (subtrahend.)

Here there are 8 tens in the subtrahend, and only 5 in the minuend; therefore we cannot subtract the former collection from the latter. But 8 tens must be subtracted as well as the other collections composing the subtrahend; therefore how are we to remedy the difficulty? This is effected in a very simple manner by a method derived from the following principle: that we do not alter the difference of two numbers by increasing one of them, provided that we increase the other as much. Thus,

$$8 - 6 = 2$$

Now add 3 to each of the numbers 8 and 6, and then subtract them; or subtract $6 + 3$ or 9 from $8 + 3$ or 11; the difference is 2. Again add 4 to each; then $6 + 4$ or 10 subtracted from $8 + 4$ or 12 is still 2. Let us now apply this principle to our example. We have

$958 = 9$ hund. $+ 5$ tens $+ 8$ (minuend.)
$784 = 7$ hund. $+ 8$ tens $+ 4$ (subtrahend.)

Add 10 tens to the minuend, and in doing so, give them to that one of its collections which is deficient, that is to the tens' collection, which instead of containing 5 tens will then contain 15 tens. In accordance with our principle, we must also add 10 tens to the subtrahend; but as they are not wanted particularly in any one collection, place them in that to which they naturally belong, and which, as 10 tens is a hundred, is the collection of hundreds. Then introducing these alterations

$958 - 784 = 9$ hund. $- 8$ hund. $+ 15$ tens $- 8$ tens $+ 8 - 4 = 1$ hund. $+ 7$ tens $+ 4$;
or as we commonly express it, 174.

Again, 3495 is to be subtracted from 7002.

$7002 = 7$ thous. $+ 2$
$3495 = 3$ thous. $+ 4$ hund. $+ 9$ tens $+ 5$.

As 5 cannot be subtracted from 2, we add 10 to this latter, at the same time adding 10 to the subtrahend, which instead of 9 tens will thus have 10 tens. Proceeding, we find that we have no corresponding collection of tens to subtract these 10 tens from, we therefore add 10 tens to the minuend, at the same time adding 10 tens, or 1 hundred to the subtrahend, by which the 4 hundreds will become 5 hundreds. Continuing with the operation, we find also that we have no collection of hundreds to subtract these 5 hundreds from, we therefore add 10 hundreds to the minuend, and also to the subtrahend, which gives us in the latter 4 thousands instead of 3 thousands. We therefore have $7002 - 3495$

$= 7$ thous. $- 4$ thous. $+ 10$ hund. $- 5$ hund. $+ 10$ tens $- 10$ tens $+ 12 - 5$
$= 3$ thous. $+ 5$ hund. $+ 7$,

which we denote by 3507.

The whole operation then is simply this: Subtract each of the component collections of the subtrahend from the corresponding collection of the minuend; and if any one of those of the minuend be wanting, or not so great as the similar one of the subtrahend, make it as great by adding 10 of its own class to it; but to counteract the effect this would have on the whole remainder, add 10 of the same class to the corresponding collection of the subtrahend, or what is the same in effect, add one of the next highest class to the next highest collection of that number. Thus, if we add 10 units to the units' collection of the minuend, we must in return add what is the same as 10 units, namely 1 ten, to the tens' collection of the subtrahend; and if 10 tens be added to the tens' collection of the former, 1 hundred, which is equal to 10 tens, must be added to the hundreds' collection of the latter.

Having thus become acquainted with the principle of the operation of subtraction, we may now as in the case of addition, omit in practice the separation of the numbers into their component collections. The last example will then appear in the following form with the remainder beneath:

$$\begin{array}{r} 7002 \\ 3495 \\ \hline 3507 \end{array}$$

We commence with the units; as 2 is less than 5, we add 10 to it; then the subtraction of 5 from the sum 12, leaves 7, which we write in the units' place of the remainder. The next figure 9, with the addition of 1 to counteract the effect of the previous *borrowing*, as it is termed, or 10, is now to be subtracted; but as the corresponding collection in the minuend is wanting, we add 10; the subtraction leaves no figure for the remainder; we therefore put in 0; 1 carried to the 4 of the next collection in the minuend makes it 5, which taken from 10 (this 10 being borrowed) leaves 5; and 1 carried to 3 and subtracted from 7 leaves 3. Hence the whole remainder is 3507.

The reason of the ordinary rule will now be apparent: Write the subtrahend under the minuend, so that the units of both shall be in one column, the tens in another, the hundreds in another, and so on: subtract every figure in the lower number from the one over it in the upper, and write the remainder under it. When the figure in the upper is the smaller, add ten to it, observing at the same time to increase by 1 the next figure to the left in the lower number.

There is a method in use of subtracting numbers by means of what is called their arithmetical complement; in peculiar cases where several additions and subtractions are to be effected it furnishes us with a more expeditious mode of obtaining the result of them all by the performance of only one operation. For an account of it, see COMPLEMENT, *Arithmetical*.

MULTIPLICATION.

When the same number is to be added together several times, the addition assumes the name of *multiplication*. Thus, if 4 eights are to be added together, we say that 8 is to be *multiplied by* 4, or taken 4 times; and we may find the result, according to the ordinary rule, thus:—

$$\begin{array}{r} 8 \\ 8 \\ 8 \\ 8 \\ \hline 32 \end{array}$$

The number to be multiplied, 8, is called the *multiplicand;* the number by which it is to be multiplied, or that denoting how many times it is to be taken, 4, is called the *multiplier*, and the result of the operation, 32, is the *product*. The two former are also called the *factors* of the product, which is itself termed a *multiple* of each. As we employ the symbols + and — to represent the operations of addition and subtraction, we use × to denote that of multiplication. Thus 2 × 2 is a short mode of representing, 2 multiplied by 2.

It is evident that were the multiplicand and multiplier large numbers, the formation of their product by the repeated addition of the multiplicand would be an excessively tedious mode of operation; in order therefore to abridge it, we separate that number into its several component collections, and taking each of them individually the number of times denoted by the multiplier, we add together the various results, and the sum thus obtained is the product required. For instance, suppose that 23 is to be taken 4 times, or multiplied by 4; we shall evidently effect this by first taking 3, 4 times, and then taking 2 tens or 20 the same number of times, and the operation may be performed thus:—

$$\begin{array}{lcl} 2 \text{ tens} & + & 3 \\ 2 \;.. & & 3 \\ 2 \;.. & & 3 \\ 2 \;.. & & 3 \\ \hline 8 \text{ tens} & + & 12 = 92 \end{array}$$

In a similar manner we find the product of 5,348 by 6:—

$$\begin{array}{lclclcl} 5 \text{ thous.} & + & 3 \text{ hund.} & + & 4 \text{ tens} & + & 8 \\ 5 \;.. & & 3 \;.. & & 4 \;.. & & 8 \\ 5 \;.. & & 3 \;.. & & 4 \;.. & & 8 \\ 5 \;.. & & 3 \;.. & & 4 \;.. & & 8 \\ 5 \;.. & & 3 \;.. & & 4 \;.. & & 8 \\ 5 \;.. & & 3 \;.. & & 4 \;.. & & 8 \\ \hline 30 \text{ thous.} & + & 18 \text{ hund.} & + & 24 \text{ tens} & + & 48 = 32088. \end{array}$$

We can now therefore multiply any number however great, by any other which is less than 10; but, from the preceding examples, it must be apparent that our object would be greatly facilitated did we previously possess a knowledge of the product of every two of the first nine numbers. For instance, we should avoid the necessity of severally adding 6 eights, 6 fours, 6 threes, and 6 fives, if we already knew that the result of those operations would give 48, 24, 18, and 30. Hence it becomes a matter of importance to ascertain these products before proceeding any further; and for this purpose it is expedient to arrange them in a tabular form, so that they may the more easily be committed to memory. This table, the invention of which is ascribed to Pythagoras, is termed the multiplication table, and exhibits the product of any one of the nine first numbers by every one of them.

Multiplication Table.

1	2	3	4	5	6	7	8	9
2	4	6	8	10	12	14	16	18
3	6	9	12	15	18	21	24	27
4	8	12	16	20	24	28	32	36
5	10	15	20	25	30	35	40	45
6	12	18	24	30	36	42	48	54
7	14	21	28	35	42	49	56	63
8	16	24	32	40	48	56	64	72
9	18	27	36	45	54	63	72	81

The construction and use of this table are very simple. The first horizontal row contains the product of each of the first nine numbers by 1, and is of course formed by the repeated addition of unity; the second row contains the product of every one of the same numbers by 2, and is formed by the successive addition of that number; the third contains their products by 3, by the repeated addition of which it is formed, and so on. Hence, if we wish to ascertain the product of 6 by 4, we look in the fourth row, or that opposite 4, till we come to the sixth column, or that headed by 6, in which stands 24, the product required. We express this generally by saying that the product is found in the row opposite to the multiplier, and the column headed by the multiplicand.

In the sixth row and the fourth column stands 24, the product therefore of 4 by 6; and in the fourth row and the sixth column, as we have already found, stands also 24; hence the product of 4 by 6 is equal to the product of 6 by 4; or more shortly

$$4 \times 6 = 6 \times 4$$

By a similar inspection of the table we find that

$$5 \times 3 = 15$$
$$3 \times 5 = 15$$

Therefore,

$$5 \times 3 = 3 \times 5.$$

The same will be found to be the case with every pair of factors in the table; hence, in multiplying any two of the first nine numbers, it is immaterial which we make the multiplicand, and which the multiplier; for the result will be the same in both cases.

This remark we deduce from actual observation; we can show that it *is* true by trying it on any of the numbers in question; but we will now prove that it *must* of necessity be so, that it cannot be otherwise. Let us take the case of 5 and 3; write the figure 1 five times in the same line, and do this three times, placing the lines one beneath the other, thus:—

1, 1, 1, 1, 1,
1, 1, 1, 1, 1,
1, 1, 1, 1, 1.

This assemblage of units represents the product of 5 by 3, for it contains 3 rows of 5 units each, or 5

units repeated 3 times. But instead of reckoning the number of horizontal rows it contains, let us count the vertical columns; of these there must of course be 5, for each column is made up of 1 of the 5 units which are in each row; and as the number of rows is 3, each column must contain 3 units; therefore counting in this way, the assemblage contains 5 columns of 3 units each, or 3 units repeated 5 times, and represents therefore the product of 3 by 5. But as we have seen, the same collection represents the product of 5 by 3; hence the product of 5 by 3 must be equal to that of 3 by 5, which we find to be the case.

This mode of demonstration is evidently not confined to the particular numbers which we have applied it to; it may be extended to any whatsoever, by simply imagining a line to be formed containing 1 repeated as often as there are units in the multiplicand, and conceiving as many of these lines to be taken and placed one beneath the other as there are units in the multiplier. Reckoning the assemblage of units thus obtained by rows, it will, from the nature of its formation, represent the product of the multiplicand by the multiplier; but if we suppose it to be divided into columns, we perceive that there must be as many columns as there are units in each row, and that each column must contain as many units as there are rows; in other words, the assemblage must consist of a column containing as many units as there are units in the multiplier, repeated as many times as there are units in the multiplicand, and will represent the product of the multiplier by the multiplicand, if we may use the expression. But it also represents the product of the multiplicand by the multiplier; hence in multiplying any two numbers, it is indifferent which of them we make the multiplier; for the product obtained in both cases is the same.

We may in practice omit the decomposition of the multiplicand into its component parts, and when the product of any of its figures by the multiplier consists of more than one digit, instead of writing down the whole of the product, we put down, as in addition, only the units' digit, and carry the other to be added to the next product. The following example will illustrate this method, and afford us an opportunity of noticing a peculiar case of multiplication: suppose 3640 is to be multipled by 8; we write the multiplicand and multiplier under one another, as in addition, thus,

$$\begin{array}{r} 3640 \\ 8 \\ \hline 29120 \end{array}$$

We then multiply the first figure of the multiplicand, 4, by 8, which gives 32, or 2 to write down and 3 to carry; but as this 4 represents 4 tens, the product must of course represent 32 tens; we must therefore write 0 after the 2, in order that that figure may come into its right place. The product of 6 by 8 is 48, which, adding the 3 left to be carried at the last operation, becomes 51; writing down the 1, we carry the 5 to the next product 24, which thus becomes 29, the whole of which, it being the last product, we put down. We observe from this example, that in multiplying a number which contains one or more final cyphers, we commence with the first significant figure, and after finishing the operation, subjoin to the result the number of cyphers which are annexed to the multiplicand. In a similar manner, if any cyphers occur in the middle of the multiplicand, we must fill up the corresponding places in the product with the same number, unless indeed we happen to have a significant figure to carry to any one of them from the preceding partial product.

We may now perceive the reason of the following rule for the multiplication of numbers, when the multiplier consists only of a single digit:

Write the multiplier under the units' digit of the multiplicand; find in the table the product of the units' digit of the multiplicand by the multiplier; write the units' digit of this product immediately under the multiplier; find the product of the next digit of the multiplicand by the multiplier, add to it the tens' digit of the former product, write the units' digit of the number thus found, to the left of the digit last set down, and proceed as before.

The following may be taken as exercises:—To prove that $956 \times 6 = 5736$; $8200 \times 9 = 73800$; and that $7012 \times 5 = 35060$.

According to our system of notation, we increase the value of any figure 10 times by merely moving it one place further from the right; and as to multiply any number by 10, it is only necessary to render each of the collections of which it is composed 10 times greater, in other words to change its units into tens, its tens into hundreds, and so on: it is evident that we shall effect this operation by subjoining a 0 to the multiplicand, since by so doing we advance each of its significant figures one place further from the right. Similarly, we multiply a number by 100, by annexing to it 2 zeros; for we thus move each of its figures two places further from the right, and consequently increase their value 100 times. We therefore perceive that to multiply a number by 10, 100, 1000, 10000, &c., it is requisite only to attach to the right of the multiplicand as many zeros as are contained in the multiplier.

When the significant figure of the multiplier is greater than 1, the operation is decomposed into two separate ones. For instance, suppose that a number is to be multiplied by 500, or in other words by 100 times 5, we multiply it first by 5, and then increase the value of the product 100 fold, by subjoining 2 zeros to it. Thus, 347 is to be multiplied by 500,

$$\begin{array}{r} 347 \\ 500 \\ \hline 173500 \end{array}$$

The product of 347 by 5 gives 1735, to which we annex 2 zeros. We thus deduce the following general rule for the multiplication of a number by another, which consists of a single digit followed by one or more zeros: Multiply the multiplicand by the significant figure of the multiplier, and write after the product as many zeros as occur in the multiplicand.

This principle will apply to the case in which the multiplier is any number whatsoever, by considering separately each of the collections of which it is composed. Thus, suppose that we have to multiply 793 by 345, or to take 793, 345 times, that is, to take it 300 times, 40 times, and 5 times, and add the results together, or in other words to multiply it by 300, 40, and 5, and add the products together. This reduces the operation to three separate ones, all of which we can perform, because the multiplier has but one sig-

nificant figure in each. Arranging the numbers as in addition, we have

$$\begin{array}{rcl} 793 & & \\ 345 & & \\ \hline 3965 & = & 5 \times 793 \\ 31720 & = & 40 \times 793 \\ 237900 & = & 300 \times 793 \\ \hline 273585 & = & 345 \times 793 \\ \hline \end{array}$$

In this operation we multiply 793 successively by the collections of units, tens, and hundreds which compose the multiplier, observing, according to the rule we have given, to subjoin 1 zero to the product given by the tens, and 2 zeros to that given by the hundreds. The addition of the partial products gives the whole products required. But as the zeros which we have annexed, count for nothing in this addition, we may evidently dispense with writing them at all, provided that we take care to put into its proper place the first figure of the partial product given by each of the significant figures of the multiplier, that is to say, the product given by the tens' digit of the multiplier, in the tens' place, that given by the hundreds' in the hundreds' place, and so on.

From this we deduce the following general rule for the multiplication of any two numbers whatsoever: Write the multiplier under the multiplicand, units under units, tens under tens, &c. Write down the product of the multiplicand by the units' digit of the multiplier, observing that its units' digit shall be under the units' digit of the multiplier. In like manner write down the product of the multiplicand by the tens' digit, observing that its units' digit shall be under the tens' digit of the multiplier; proceed thus, and, when all the partial products are set down, add them up as they stand, for the whole product.

DIVISION.

The product of two numbers is formed by the repeated addition of one of them as many times as there are units contained in the other; in other words, the two factors are given, and the product is required. Suppose now that we have the product and one of the factors given, and that we wish to find the other; the second factor is simply the number which denotes how many times the first must be added to form the product; consequently we shall find it by subtracting the first factor from the product till we can subtract it no longer. For instance, if we wish to know how many times 16 must be added in order to make 64, in other words, how many times 64 contains 16, we have only to subtract 16 from 64 as often as we can; thus,

64
16 . . first subtraction.
—
48
16 . . second subtraction.
—
32
16 . . third subtraction.
—
16
16 . . fourth subtraction.
—
0

As we can only subtract 16, 4 times, we conclude that it is contained in 64, 4 times. Hence, in order to find how many times one number contains another, it is only necessary to subtract that other repeatedly from the first. The number of times this operation can be performed is the number of times required. But the application of this method to cases in which the one number contained the other a great many times would be exceedingly laborious; we therefore substitute a more compendious one, termed *Division*, analogous to the mode of abridging the repeated addition of the same number by means of multiplication, and alike suggested by the principle of numerical arrangement. This operation is then, strictly speaking, confined to large numbers, but it is usually, for the sake of uniformity, said to apply to all. Thus, in the preceding example, our object has been to *divide* 64, which is termed the *dividend*, by 16, or the *divisor*, in order to obtain the *quotient* 4; and the operation may be shortly denoted by writing $64 \div 16$, or, more commonly, $\frac{64}{16}$.

Again, suppose that we wish to divide 111 by 37:

111
37 . . first subtraction.
—
74
37 . . second subtraction.
—
37
37 . . third subtraction
—
0

As the remainder we obtain after subtracting 37 3 times is 0, we conclude that the quotient is 3.

It is evident that when the dividend does not contain the divisor as many as ten times, which can of course be easily ascertained by a simple inspection of the two numbers, and when the divisor consists of a single digit, the quotient may be found by reference to the table of products in the multiplication table. Suppose, for instance, that it is required to know how often 8 is contained in 56: passing down the eighth column in the table until we come to 56, we find that that number stands in the seventh row, or that opposite to 7, which is therefore its other factor, and denotes the number of times that it contains the first. We may perceive, by an inspection of the same table, that there are some numbers which cannot be exactly divided by others. For instance, as the seventh row, or that which contains the multiples of 7 does not include 40, therefore, it is evident that 40 is not a multiple of or divisible by 7; and as 40 lies between 35 and 42, both of which are multiples of 7, the greatest multiple of 7 that 40 can contain is 35, the factors of which are 5 and 7.

Let us now proceed to divide 1656 by 3; or, in other words, to find a number such that the multiplication of its units, tens, hundreds, &c. by 3, will give a product consisting of the units, tens, hundreds, &c. of the dividend 1656.

It is clear that this required number cannot contain a collection of any order higher than that of thousands, for if it had one of ten thousands, there would be also a collection of ten thousands in the product, which there is not. It is equally clear that it cannot contain a collection of so high an order as that of thousands, for if it had only one thousand, the product

would contain at least 3 thousand, which is not the case. Hence the thousand of the dividend must necessarily result from the multiplication of the hundreds' collection of the quotient by 3; therefore we shall obtain the number of the hundreds contained in the quotient by dividing that of the hundreds of the dividend by three. But 16 is not divisible by 3; we therefore find the greatest number in it which is, in other words, its greatest multiple of 3, which is 15, and the quotient of this by 3 is 5. But 5 hundreds, multiplied by 3, gives 15 hundreds, and the dividend 1656 contains 16 hundreds; hence the difference, 1 hundred, must have entered into the dividend in consequence of being *carried* over from the tens' place, in the formation of that number through its multiplication by the divisor. If now, from the whole product, we subtract what we have found to have been one of the partial products obtained during the performance of that operation, namely, 15 hundreds, or 1500, the remainder, 156, will contain the products of the units and tens of the quotient by the divisor; and therefore all we have to do now is to find that number, the multiplication of whose units and tens by 3 will give 156—a question precisely similar to that we originally set out with.

Having found the first figure of the quotient of this second dividend, in a similar manner to that in which we found it in the former case, we subtract its product by the divisor from the dividend, and the remainder which we obtain we make a third dividend, upon which we operate as upon the two preceding. We continue this method until we have no remainder left of which to make a dividend, when we have subtracted the divisor from the original dividend as often as we can, and therefore have finished the operation.

The following is a connected view of the operation.

$$\begin{array}{rrl}
\text{(dividend)} & 1656 & \left.\right\} \ \underline{\ \ 3} \ \text{(divisor)} \\
 & \underline{1500} & \left.\right\} \ 552 \ \text{quotient} \\
 & 156 & \\
 & \underline{150} & \\
 & 6 & \\
 & \underline{6} & \\
 & 0 &
\end{array}$$

The arrangement of the divisor and dividend is perfectly arbitrary; that which we have followed is the most convenient as facilitating the mental multiplication of the divisor by the figures of the quotient.

Let us take another example:

$$\begin{array}{rl}
1535 & \left.\right\} \ \underline{\ \ 5} \\
1500 & \left.\right\} \ 035 \\
\underline{35} & \\
0 &
\end{array}$$

Here we perceive that upon subtracting the 1500, or the product of the hundreds' figure of the quotient by 3, we obtain for remainder only 3 tens and 5; now 3 tens not being divisible by 5, we can have no tens' figure in the quotient, we must therefore write a 0 in the place of that collection, in order that the other collections may fall into their right places. Hence, whenever we obtain a partial dividend which is not divisible by the divisor, we must insert a cypher in the place appropriated to its collection in the quotient. The rest of the operation is as usual.

Let us now proceed to a case in which the divisor consists of more than one digit, for instance, the division of 57981 by 251. The quotient evidently cannot contain any collection of a higher order than that of hundreds; and the number of that collection which it does contain, must be such that, multiplied by 251, it may give 579 hundreds, or the nearest multiple of 251 below that number, which 579 contains. It is therefore 2; but the product of 2 hundreds by 251 is 502 hundreds, and the dividend contains 579 hundreds; the difference, 77 hundreds, must enter into the dividend by having been *carried* over through the multiplication of the tens and units of the divisor by the quotient. Subtracting the partial product 502 hundreds, or 50200 from the whole product 57981, we obtain the remainder 7781, which must contain the products of the tens and units of the quotient by the divisor; therefore, having found the hundreds of the quotient, all that we now have to do is to find a number which, multiplied by 251, will give 7781. To effect this, we proceed as before, and find the first figure 3 of this second quotient; multiplying the number which it expresses by the divisor, and subtracting the partial product thus obtained from the whole product 7781, we procure a remainder 251, which is the product of the units' figure of the quotient by the divisor. In this we proceed as before, until the whole operation is finished. The following exhibits a connected view of it:

$$\begin{array}{rl}
57981 & \left.\right\} \ \underline{\ 251} \\
\underline{50200} & \left.\right\} \ 231 \\
7781 & \\
\underline{7530} & \\
251 & \\
\underline{251} & \\
0 &
\end{array}$$

We find the successive digits in the quotient by guessing at them as well as we can. When we multiply the divisor by the digit guessed, if the product be greater than the partial dividend, the digit is too great; when we subtract, if the remainder be greater than the divisor, the digit is too small.

From these various considerations we may perceive the reason of the ordinary rule for the division of any one number by any other: Write the divisor on the right hand of the dividend; from the left of the dividend mark off the smallest number of digits that make a number not less than the divisor, find by trials the greatest number of times that the divisor is contained in this period, and write the result for the highest collection of the quotient beneath the divisor, but separated from it by a line: multiply the divisor by this digit, and subtract the period from the period marked off; bring down to the right of the remainder the next digit in the dividend, and proceed with the number thus formed as with the first period, writing the result as the second digit in the quotient: and proceed in the same way to find the other digits of the quotient.

The subject of Arithmetic will be continued under the articles, *Whole Numbers, Measure, Fractions, Decimal Fractions*, &c.; and the application of the science to the purposes of commerce will be explained under the heads of *Compound Numbers, Rule of Three, Interest*, &c.

ARITHMETICAL MACHINE. The various popular instruments employed for arithmetical purposes have been described and illustrated under our article

ABACUS; under which head our readers will also find an account of Mr. Babbage's extraordinary calculating instrument.

ARITHMETIC, *harmonical*, is that part of the doctrine of numbers which relates to the comparison, reduction, &c., of musical intervals.

ARITHMETIC, *specious*, is that which gives the calculus of quantities; using letters of the alphabet instead of figures to denote the quantities; and coincides with what we usually call algebra, or literal arithmetic. Dr. Wallis has joined the numeral with the literal calculus; and by means of it demonstrated the rules for fractions, proportions, extraction of roots, &c., under the title of *Elementa Arithmeticæ*.

ARM. See ANATOMY and BRACHIUM.

ARM, *fore*, that part lying between the elbow and the wrist.

ARM *of a horse;* the fore thigh.

ARM; each extremity of a bibb or bracket.

ARM *of an anchor;* that part of an anchor to which the palm is welded.

ARMENIUS LAPIS, or ARMENIAN STONE; an opaque sort of stone of a greenish blue colour, like the lapis lazuli. It is used as a purgative.

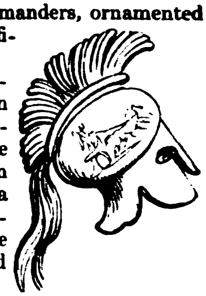
ARMENIAN BOLE; a native bole or earth brought from Armenia, commonly called bole armoniac. It is a fat kind of earth of considerable use as an absorbent and astringent.

ARMILLARY SPHERE; an artificial sphere so called from armilla, a bracelet, or ring, because it is composed of a number of circles of metal, wood, or paper, representing the several circles of the sphere of the world, put together in their natural order. For a more particular description of this instrument and its use, see ASTRONOMY.

ARMILLARY TRIGONOMETER; an instrument invented by Mr. Munro Murray, and improved by Mr. Ferguson, consisting of five semi-circles divided and graduated so as to solve many problems in astronomy.

ARMS. Man has not, like many animals, received from nature any member intended particularly as a weapon. He is obliged to use artificial means to increase his strength when he attacks, as well as to screen his body, which nature has left unprotected. Arms were, therefore, an early invention; perhaps, in the first instance, as a means of defence against animals. They were soon used, however, for the purpose of conflict between man and man. The first and most natural of all arms are the club and the sling. Every one naturally uses missiles as means of offence, and the sling adds force to the cast. In the history of the arms of all nations, we find invariably that man, beginning with the means of injury in the close struggle, endeavours continually to invent weapons which shall take effect from greater and greater distances. In consequence of the progress made in this way, dexterity always takes at last the place of courage. Nature has given to man only one weapon, in a limited sense of the word—the arm, used in boxing; and this can be made truly a weapon only by the dexterity acquired by long training. The art of boxing, moreover, is of use only against men. Within its sphere, indeed, it is very effectual. As soon as men learned the use of the metals, they worked them into pikes, spears, lances, and soon afterwards into swords and armour. Of this last, part only was at first made of metal, but the proportion went on increasing till at last a complete suit of iron came into use. The first improvement on the sling and the bow was the cross-bow. Still later came the large engines employed by the ancients, and called *catapultæ*, *balistæ*, &c. These would produce effect at the distance of 1000 feet. But the discovery of gunpowder changed the character of arms. Objects 6000 paces distant could now be reached, and obstacles overthrown with ease, the destruction of which formerly cost the labour of years. But the early defensive armour is much too curious to be passed over with this brief historical notice, and we propose to describe the principal arrangements adopted for this purpose both amongst the Greeks and Romans as well as our own ancestors. We cannot do better than commence with the helmet, especially as we find one very similar to the earliest of which we have any authentic record, employed in some of our horse regiments in the present day.

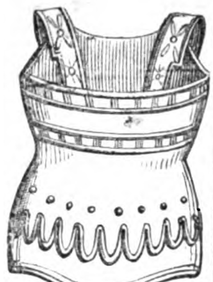
The Roman helmets, though commonly distinguished by the elegance of the Grecian, were of various forms; and those of commanders, ornamented with mythological and other figures of gold in high relief.



One of the simplest of these decorated helmets is represented in the annexed engraving, and combined with the splendour of the other equipments of the Roman legions, must have given them a very imposing aspect, which undoubtedly had its influence on the minds of their less civilized and more simple opponents.

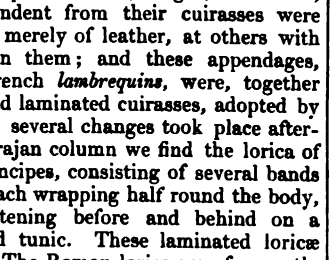
The round decorated helmet, with chain-mail attached for the protection of the neck, though for ages a most important part of the defensive armour of the knights of every nation of Christendom, was probably of eastern origin, and might have been introduced into more western countries by the Crusaders. A very beautiful illustration of the form of an eastern helmet is given in the accompanying figure. Plain round helmelts appear, however, to have been worn occasionally by the Roman gladiators, and to have formed part of the defensive armour of the common soldiery in most nations of Europe in later ages, and even in England so late as the seventeenth century. But the changes in military tactics, by the improvements in artillery and fire-arms, have caused the abolishment even of this last vestige of the heavy armour of our forefathers. We of course except the helmets worn in some of our horse regiments, to which allusion has already been made.

The ancient body armour was picturesque in its appearance, but not so well caculated for resisting a missile weapon as that worn by our horse-guards and lancers in the present day. In the earliest forms wood and the skins of animals were resorted to, and the latter of these materials was rendered so hard by exposure to the wind and sun, that we are told by a distinguished classic author, that the lance could not pierce the wearer. Horsehair was also employed for the protection of the body, and though not fitted to resist a direct thrust, effectually protected the soldier from the action of any cutting instrument. It was also very light. The cuirasses were made of folded linen or cloth; brass and iron were



most commonly of two pieces, and joined by a buckle at the shoulders, as in the accompanying wood-cut. These were altered, through their heaviness, to plates upon leather or cloth; and both these and chain-mail, but not interlaced, says Dr. Meyrick, also occur. Gold plates distinguished the Greek and Roman generals. The soldiers on the Trajan column wear a short leathern tunic, like a waistcoat, upon which plates of metal were sewed. The plates were sometimes superseded by small chains. The Etruscan cuirasses were plain, scaled, ringed, laminated, or quilted. Dependent from their cuirasses were straps, sometimes merely of leather, at others with pieces of metal on them; and these appendages, termed by the French *lambrequins*, were, together with their plain and laminated cuirasses, adopted by the Romans. But several changes took place afterwards. On the Trajan column we find the lorica of the hastati and principes, consisting of several bands of brass or steel, each wrapping half round the body, and therefore fastening before and behind on a leathern or quilted tunic. These laminated loricæ were very heavy. The Roman lorica was frequently enriched on the abdomen with embossed figures, on the breast with a Gorgon's head for an amulet, on the shoulder-plates with scrolls of thunder-bolts, and on the leather border which covered the top of the lambrequins, with lions' heads formed of the precious metals. The compact cuirass was made to open at the sides, where the breast and back plates joined by means of clasps and hinges.

Dr. Meyrick observes, that in ancient times the shape of the shield had much to do with the mythology of the people, and therefore were circular to represent the sun, and crescent-like to imitate the moon; of this latter species of shield, from its great rarity, we give a figure.



The ivy-leaf was sacred to Bacchus, and it is most probable that the Greeks derived the pelta, which Xenophon describes as of the same form to his earliest worshippers. The first shields were of basket-work, to which succeeded light wood. Ox leather, covered with metal plates, was however the most useful material. The middle had a plate of metal, often furnished with a thread of metal, turned in a circle or spirally. At first the shield was carried by a piece of leather, suspended from the neck over the left shoulder. This apparatus often appears upon Etruscan monuments. The handles of shields, says Herodotus, were inventions of the Carians. When, after war, the shields were suspended in the temples, the handles were taken away to prevent their being of service in sedition. Æschylus says, that bells were sometimes added to shields to affright enemies by the sudden sound, but Dr. Meyrick could not discover a single specimen. The Peloponnesians engraved their initials upon their shields, in order to distinguish themselves in battle. In a similar manner upon their coins there often occurs only a monogram of the two first letters of their names.

We come now to our own country, and it may in this division of our subject be advisable to go somewhat more into detail.

The arms in use among the ancient Britons were slight, and unfit to withstand the Romans in a close encounter; though in light skirmishes, prudently made, the Britons generally gained considerable advantage. Their young men were not only trained to the use of arms in early youth, but continued in the exercise of them for a very long period; and were always ready to appear, when called by their leaders into actual service. Their very diversions and amusements were of a martial and a manly cast; and the javelin they used in hunting was a principal weapon in the field of war. They had neither helmets, breastplates, nor defensive armour, but a light shield. Cæsar tells us they had a dart or javelin, which they threw from their war chariots to annoy the enemy; with a short spear for the infantry, that had a ball at the nether end filled with brass; this they shook with great violence before the battle, in hope to intimidate the enemy; and again, when they engaged the cavalry: to the upper end of it a thong was fixed, that when used as a missile weapon it might be recovered, and again used in the close encounter. They had also long and broad swords, without points, designed only for cutting, which were slung by a chain over the left shoulder; and occasionally a short dirk fixed in their girdles. The scythes that were sometimes fastened to their chariot wheels, may be ranked among their offensive arms.

The ancestors of the Saxons, in their native woods, we are told, transacted no business, public or private, without being completely armed; and the custom of wearing swords on all occasions prevailed in every country of which the Germans took possession.

The early Saxons, previous to their arrival in Britain, beside the buckler and the dagger, used a sword bent in the manner of a scythe; but their descendants soon changed it for one that was long, straight, and broad, double-edged, and pointed.

The Saxon infantry were not all furnished with the same offensive weapons; some being provided with spears, others with axes, and not a few with clubs, beside swords, which were common to them all. Their shields were generally of the middle size, for the most part oval, always convex, and having a sharp spike projecting from the centre; with which, while they defended themselves, they annoyed their enemies. They fought with their swords and shields, much like the gladiators of the Romans; and in the earliest times had nothing like defensive armour, which they seem to have adopted about the eighth or ninth century. Some alteration in our national arms probably took place on the arrival of the Danes. Their swords were both longer and larger than the Saxon swords; the lance had a slight difference; and they appear to have brought the battle-axe into more general use. Verstegan enumerates the cross-bow as a Saxon weapon, but had no good authority for the assertion; as it neither appears in any ancient history or delineation, that the Saxons ever were acquainted with it. And though they used the common bow when following the chace, they never brought it to the field of battle. Their cavalry were armed with greater uniformity than those who fought

on foot; carrying in their right hands long spears, and at their left sides a sword. They were also better provided with defensive armour.

Arms, in *Heraldry*, are usually connected with the rank or history of the bearer. It implies, any coats of arms; any signs of arms, or armour, painted on shields, targets, banners, &c.

Arms are of various kinds, as arms of dominion, borne by kings and emperors.—Arms of pretension, borne by sovereigns who are not in possession of the dominions they represent; as the arms of France, formerly quartered in those of England.—Arms assumptive; such as a man may of right assume with approbation of his sovereign. Arms of patronage; such as governors of provinces, &c. add to their arms. —Arms of alliance; such as are taken by the issues of heiresses to show their descent, paternal and maternal.—Arms of succession, taken by those who inherit certain fiefs or manors.—Arms of adoption; those taken from another family to be quartered with the paternal one.—Arms paternal and hereditary; such as are transmitted from the first obtainer to his son, grandson, great-grandson, &c.—Arms of concession; augmentations granted by sovereigns.—Arms canting or allusive, whose figures allude to the names, professions, &c.; as, a trevet for a person named Trevet, three cups for one named Butler, &c. We may cite one instance, to shew the importance which our ancestors attached to these almost "bygone distinctions." We allude to the celebrated case of Sir Richard le Scrope against Sir Robert le Grosvenor, in the reign of Richard II., about a coat of arms, viz. *azure* a bend *or*. This case was tried before the Constable and High Marshal of England, and others commissioned for the purpose. After the evidence of a large portion of the nobility and gentry, the sentence of the court (at the end of three years) was, that Sir Robert le Grosvenor should bear the said arms with a bordure, argent: who thinking himself injured by that sentence, appealed to the king, before whom, by his commissioners, the whole pleadings were reviewed; and at length it was decided that Sir Richard le Scrope should continue to use the same arms, and that Sir Robert le Grosvenor should use the said arms with a bordure, as in the sentence, or else instead of a "*bend, or,*" he might bear "*a garb, or,*" from his consanguinity to the Earls of Chester; whereupon Sir Robert ever after bore for his arms "*Azure a Garb, or,*" and the same have continued by his descendants to this day, of whom the present Earl Grosvenor is one.

Arnabos; an aromatic drug, sometimes employed as a substitute for cinnamon.

Arnaldia; a disease formerly known in England, one of the symptoms of which was a loss of the hair.

Arnotta; a drug of which a good deal is used in this country for the purposes of the dairy. Cheese dyed with it is said to have its flavour as well as its colour improved by the mixture. The arnotta employed by the dyers is of a dark red colour. It is formed from the pulp of the bixa.

Arnulphin; a coin formerly used in France. It was estimated at about a ducat and a half.

Arroba, or Arrobe; a variable weight used in Spain and Portugal. In the former country it is equal to 25, in the latter to 32 of their respective pounds. It is also a Spanish liquid measure, which, as regulated for wine, &c. by the standard of Toledo contains 1237¼ Spanish, or 981 English cubic inches, and equals 8 azumbras, or 32 quartillos. The arroba menor, or arroba of oil, measures 966¾ Spanish, or 771 English cubic inches, and is divided into 4 quartillos. The arroba is a name also given to one of the corn measures of Morocco.

Aroph; a term employed by the ancient alchemists, both for saffron, mandragora, and chemical flowers.

Aroura; a Grecian measure of length amounting to fifty feet.

Arpeggio, in *Music*. This term, which is of frequent occurrence, implies that the tones should be sounded distinctly, beginning at the lowest.

Arpent; a French measure of 100 perches.

Arquatus Morbus; the ancient name for jaundice.

Arquebus. This missile weapon was sometimes employed in the hand, and at other times used for the defence of a fort. It had a matchlock.

Arquebusade. A water under this name has long been fashionable, both as a medicine and a cosmetic. One of its principal ingredients is alcohol.

Arrache', in *Heraldry*; a representation of a plant torn up by the roots.

Arrest, in the *Veterinary Art*; a disease seated between the ham and posteria.

Arrhaphon; a skull in which the bones are unconnected by sutures.

Arriagi; the ancient name of camphor.

Arrondee, in *Heraldry*; a cross, consisting of sections of a circle, the whole of the curves being in the same direction.

Arrotino; a celebrated marble figure now at Florence, the history or design of which is involved in obscurity.

Arrow; the well known missile which is discharged from a bow, the pointed part of which is called the arrow-head. Bundles of arrows are called sheaves.

Arrow Stick. A rod employed in surveying.

Arschin; a Chinese measure of length, equal to two feet eleven lines.

Arsenic is a metal of very common occurrence, being found in combination with nearly all of the metals in their native ores. It is of a bluish-white colour, readily becoming tarnished on exposure to air, first changing to yellow, and finally to black. In hardness, it equals copper, is extremely brittle, and is the most volatile of all metals, beginning to sublime before it melts. Its specific gravity is 5736. It burns with a blue flame and a white smoke, emitting a strong smell of garlic. It commonly bears the name of *black arsenic*, and is prepared from the white arsenic of commerce, by heating this substance with carbonaceous matter, and allowing the volatile arsenic to condense in an adjoining vessel. Arsenical pyrites, a very abundant natural substance, is also advantageously used in the preparation of arsenic, in which case iron filings and lime are added, to engage the sulphur, and prevent its sublimation along with the arsenic. Native arsenic has been found in the veins of primitive rocks in several countries, but in small quantities, and generally alloyed by the presence of iron, silver, or gold. This metal is used in metallic combinations, when a white colour is desired. With oxygen, arsenic forms two compounds, both of which, from their property of combining with alkaline and earthy bases, are called *acids*. The

arsenous acid, the most important of the two, is the *white arsenic* of the shops. It is usually seen in white, glassy, translucent masses, to which form it is reduced by fusion from a powdery state. It is one of the most virulent poisons known, not only when taken into the stomach, but when applied to a wound, or even when its vapour is inspired. It is found native in small quantities, but is obtained for use from the roasting of several ores, particularly from that of cobalt and arsenical pyrites. The arsenous acid is condensed in long horizontal chimneys leading from the furnaces where these operations are conducted, and usually requires a second sublimation, with the addition of a little potash, to deprive it of any sulphur it may contain. Its manufacture has been chiefly confined to Bohemia and Hungary. Persons brought up from their youth in the works live not longer than to the age of 30 or 35 years. Knowing the deleterious nature of their occupation, they are so careless, that we have seen them cleaning their plates, &c. in wells, over which a skull was painted, to warn every body that the water contained arsenic. Besides its use in medicine, and as a ratsbane, it is much employed as a cheap and powerful flux for glass; but, when too much is added, it is apt to render the glass opaque, and unsafe for domestic use. Arsenite of potash, mingled with sulphate of copper, affords an apple-green precipitate, called *Scheele's green*, which, when dried and levigated, forms a beautiful pigment. With sulphur arsenic forms likewise two definite compounds—the realgar and orpiment. The former of these contains the smallest proportion of sulphur, and is red; the latter is yellow. They are both found native in many countries, but their supply in commerce depends upon their artificial manufacture. This is done by distilling a mixture of arsenical pyrites and iron pyrites, or of white arsenic and rough brimstone. Realgar or orpiment is obtained as the proportion of sulphur employed is greater or less. These compounds afford valuable pigments to the painter.

Arsenal; military depôt.

Arsenical Magnet; a preparation of antimony, sulphur, and arsenic.

Arshin; a Russian measure of length, equal to 315 French lines. The Chinese Arschin amounts to 302 lines.

Arsura; a classical term for the powder of a silversmith's workshop. The term was also employed by the alchemists for their dust of silver.

Arsura; the ancient name for erysipelas.

Arthritis; see Gout.

Arteriosa Vena; the pulmonary artery.

Arteriosus Canalis; a tube leading to the heart in the human fœtus.

Artery. This term is employed to describe the conical tubes which convey the blood from the heart to the various parts of the body. The arteries consist of three coats; the external, containing blood-vessels; the middle, consisting of elastic fibres, that contract and dilate; and the internal, which is a fine dense membrane that supports the fibres. By the circulation of the blood through the arteries, is produced the particular motion called the pulse, which arises from the alternate dilatation of the arteries, called the diastole, and their contraction, called the systole. The time which the fibres of the arteries take in performing their systole, that is, their return to their natural state, is the distance between two pulses. The heart discharges the blood into two great blood-vessels, called the arteria pulmonalis and the aorta.

The arteria pulmonalis, or pulmonary artery, rises from the right ventricle of the heart, and dividing itself to the right and left, carries the blood by innumerable ramifications through the lungs.

The aorta goes from the left ventricle of the heart, and is divided into the aorta ascendens and the aorta descendens. The aorta is called ascendens from the point where it leaves the heart to its great curvature or arch, from which it is principally distributed to the thorax, the head, and the upper extremities. The aorta descendens is the remaining part of this trunk from the arch to the os sacrum, or the bifurcation. It is distributed to the diaphragm, abdomen, and lower extremities. From each of these divisicns arise what are called original or capital branches, from which smaller branches and ramifications proceed. The capital branches from the aorta ascendens are—arteriæ subclaviæ, the subclavian arteries, which run under the clavicle, or collar-bone. The carotids go from the arch of the aorta directly to the head.—The arteriæ coronariæ of the heart, are so called because they form a sort of crown on the basis of the heart. The principal subordinate branches from these are from the subclavian arteries, the mammaria interna, the mediastana, the pericardia, the diaphragmatica minor sine superior, thymica, trachealis, vertebrales, cervicales, and intercastales, and the axillary artillary, which is only a continuance of the subclavian from where it goes out of the thorax to the axilla. The carotids are divided into external and internal; the external sends out the maxillaris interna, occipitalis, temporalis, lingualis, &c. The internal sends out the opthalmic and middle cerebral arteries.

The capital branches from the aorta descendens are—in the breast, the bronchial, œsophageal, intercostal, and inferior diaphragmatic; within the abdomen, the cæliac, which divides into the hepatic, the coronaria ventriculi, and the spenic; the mesenteric superior and inferior, the emulgents, the spermatics, the lumbar arteries, &c. At the bifurcation the aorta divides into the iliacs, which are divided into external and internal. The external gives off the epigastric, femoral, tibial, &c.; the internal sends forth the sacral, gluteal, ischiatic, &c.

Arthron; any series of bones in the animal structure.

Artificial Day; the period which elapses between the rising and setting of the sun.

Artillery signifies all sorts of great guns or cannon, mortars, howitzers, petards, &c., together with all the apparatus and stores thereto belonging, which are taken into the field, and used for besieging and defending fortified places. It signifies also the science of artillery or gunnery, which, originally, was not separated from military engineering. The class of arms called *artillery* has always been the subject of scientific calculation, more than any other species, as the Italian word *arte*, in its name seems to indicate. The same name is also given to the troops by whom these arms are served, the men being in fact, subsidiary to the instruments. The other portions of an army, are *armed men*, while the artillery consists of *manned arms*. Wooden artillery appears at first view but little fitted for actual service, and yet it appears that it was used effectually in one of Auring-

zebe's campaigns in the Deccan. The commandant of a large town was nearly unprovided with cannon, having only one or two defective pieces. The town was, however, a great mart for timber. The governor securing both the timber and the carpenters, garnished his ramparts with wooden imitations or cannon; and being fully supplied with most other requisites when the imperial aimy arrived, put a good face on the business. He did more too, for he kept the secret within his own walls; and the enemy respecting the number of his train, commenced their approaches in due form, affording him thus abundance of leisure to mature his plan of defence. Every piece as soon as fired, became of course unserviceable, but he immediately replaced it by a new one. The balls from the imperial batteries were returned with the utmost facility, as, however ponderous these were, our hero was able to supply pieces of any calibre, and sent recochet shot, *selon les regles*, even with more effect than his enemy. The labours of the Carron Foundry never produced more guns in a year, than this man's ingenuity did in one siege. The enemy tired out at last, with the obstinate defence which he made from his batteries, determined to carry the place by escalade in open day. Having failed, however, in some similar enterprises, a neighbouring saint was procured, who was to head the attack, and by the sanctity of his character, to inspire the soldiers with greater zeal in a desperate cause. The holy man was raised on a platform, and carried in the rear of the forlorn hope. The governor's good luck still adhered to him. A shot from a wooden gun, when the escaladers were nearly close to the walls, overthrew the saint, and the siege was raised.

Arthrocace, in *Surgery*, is a disease of the joints, or the extremities of bones, more commonly named Spina Ventosa. When this disorder affects children, it is called Pædarthrocace.

Arthrodia, is a species of articulation, admitting of a very small degree of motion; as each bone composing the joint must have nearly a plain surface. Such is the articulation of the humerus with the scapula.

Arthrodynia, in *Surgery*, is a chronical rheumatic affection of the joints.

Arthropuosis, is a suppuration of the joints, or at least a strong tendency to form pus. In this case there is a deep-seated inflammation, obtusely painful, sometimes throbbing, and accompanied with febrile symptoms.

Arthrosis, a juncture of two bones designed for motion; called also articulation, which see,

Articulation, in *Anatomy*, the juncture or connection of two bones. Articulation is technically divided into diarthrosis, or moveable, articulation; synarthrosis, or immoveable; and amphiarthrosis, which is defined to be a compound of both the others. The immoveable connections of bones are said to be by symphysis, harmonia, suture, gomphosis, scindelesis, synchondrosis, synenrosis, or syndemosis, and syssarcosis. The moveable articulations, which alone appear to deserve that term, are divided into enarthrosis, ginglymus, and arthrodia. When the spherical head of one bone is received into a corresponding cavity of another, a joint is formed, which admits of motion in every direction, this is, what is termed enarthrosis, or more plainly a ball and socket joint, of which we gave an example in the article Anatomy, p. 80.

Artificers, those who work with the hands, and manufacture any kind of commodity in iron, brass, wood, &c., also called handicrafts and mechanics.

Artificial Lines, on a sector or scale, are certain lines so contrived, as to represent the logarithmic sines and tangents; which, by the help of the line of numbers, will solve all questions in trigonometry, navigation, &c., with tolerable exactness.

Artimourantico. While we now write, a metallic preparation under this name has received the sanction of the Bolognese Academy, and is manufacturing on a large scale for exportation from Italy. In appearance it resembles gold of 18 carats purity. It is an alloy of tin, sulphur, bismuth, and copper.

Artomeli, a kind of cataplasm prepared of bread and honey, applied chiefly to the præcordia.

Arts, *Fine*. We propose under this head to furnish our readers with a connected view of the progress of painting and sculpture in this country; and to render this really useful to the student and amateur, it will be advisable to trace somewhat of their early history in connection with their cultivation in Greece and Rome. Some have doubted whether sculpture or painting should have the priority in point of historical invention; but a moment's consideration will serve to show that the first rude efforts of the artist would be directed to a selection of the block of stone nearest in point of form to the object to be represented, and as such that it would be easier to become an artist in those materials than on a flat surface where both *outline* and *relief* would be required.

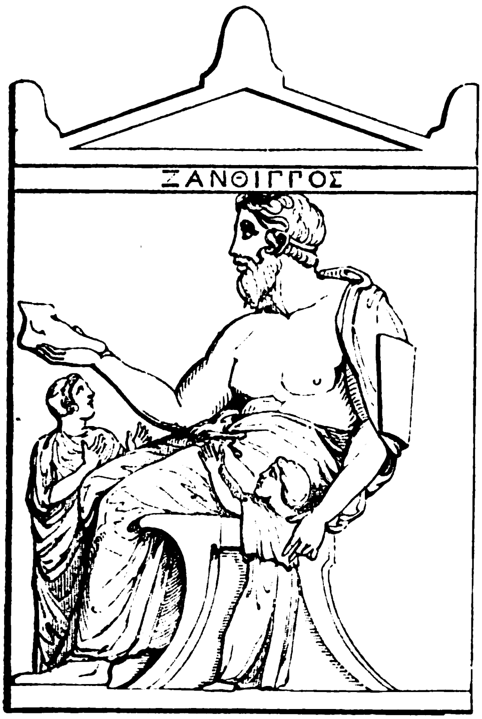
Dædalus, the first artist who acquired sufficient celebrity to have his name handed down to posterity, is said to have flourished three generations before the Trojan war; and according to the most generally received chronology, about fourteen hundred years before the Christian era. His principal and best authenticated works were large statues in wood, some of which remained until the general destruction of art under the later Roman emperors; and in spite of the rudeness of their forms, struck an intelligent traveller of the period with the grandeur and dignity of their air and character.

The spoils of the defeated armies of Xerxes in Greece, a tenth of which by immemorial custom belonged to the gods, afforded means of ample employment to the great sculptors who succeeded, among whom we find the names of Phidias, Alcamenes, Critias, Thestocles, Agoracritus, and Hegias; who were soon followed by Algelades, Callo, Polycletus, Phradmo, Gorgias, Laco, Myro, Pythagoras, Scopas, and Perelius.

Of Phidias' general style of composition, the friezes and metopes of the temple of Minerva at Athens, published by Mr. Stuart, and since brought to England, may afford us competent information; but as these are merely architectural sculptures executed from his designs and under his directions, probably by workmen scarcely ranked among artists, and meant to be seen at the height of more than forty feet from the eye, they can throw but little light upon the more important details of his art. From the degree and mode of relief in the friezes they appear to have been intended to produce an effect like that of the simplest kind of monochromatic painting, when seen from their proper point of sight; which effect must have been extremely light and elegant. The relief in the metopes is much higher, so as to

exhibit the figures nearly complete; and the details are more accurately and elaborately made out: but they are so different in their degrees of merit, as to be evidently the works of many different persons; some of whom would not have been entitled to the rank of artists in a much less cultivated and fastidious age.

A very good illustration of early basso-relievo is furnished in the architectural ornaments of the tomb of Xanthippus, father of Pericles. In this, and indeed in all the early bas-reliefs, the draperies are thin, and the folds small and distinctly formed.



One of the peculiarities of the early artists was a desire to produce powerful and striking effects by gigantic figures, and this was peculiarly displayed in the animal kingdom. The practice of placing colossal lions of stone at the entrance of a temple was both an Egyptian and Hindoo usage. Abdallatif describes two that he saw at Memphis, opposite to one another, and of proportions far beyond those of nature. He says the sight of them inspired fear, for the sculptor had maintained with perfect skill all the exactness of form and proportion. These lions, he tells us, were afterwards broken and covered with earth.

It was sometimes the practice of the Egyptians to paint their colossal statues, as we learn from Abdallatif's account of the great colossus which he saw in the ruins of Memphis. Traces of red paint are still discernible on the face of the great sphynx, and on one of the four colossal figures attached to the front of the temple of Ipsambul. Among the Greeks we find colossal statues not uncommon, and several which Pausanius mentions were 30 feet high and upwards. The people of Elis set up a bronze statue of Jupiter, 27 Greek feet high, in the Altis or sacred grove near Olympia, and the chryselephantine statue of the same deity, placed in his temple on the banks of the Apheus, was probably not less than 60 feet high. Among the Greeks the most common colossal statue was the chryselephantine, though occasionally marble, and still more frequently metal, was used for the same purpose; but as it is simply our object to show how widely this taste for colossal figures was spread, it may be enough for us to cite the celebrated work of Chares (the colossus of the sun), which was set up at Rhodes. This work of Grecian art surpassed any thing that the world has ever seen.—"It was 70 cubits high (105 Roman feet). After standing fifty-six years, it was thrown down by an earthquake, but it is still a wonder even in its prostrate condition. Few men can embrace its thumb; and its fingers are larger than most statues. Huge caverns are seen in the fractured limbs, and within them immense stones which had been put there for the purpose of keeping it steady. This enormous statue is said to have cost 300 talents, and twelve years' labour." The colossus which Nebuchadnezzar set up in the plain of Dura, was "an image of gold, whose height was threescore cubits, and the breadth thereof six cubits." Herodotus also mentions a colossal statue twelve cubits high and of solid gold.

It would be a waste of our readers' time to multiply specimens, but an instance of Greek sculpture at a later period may not be out of place.

As examples of masculine beauty and majestic dignity, the greater portion of the numerous antique statues of Minerva stand unrivalled. The accompanying illustration is a representation of one which possesses these characteristics in an eminent degree, and which is now in the Capitoline Museum at Rome.

The attitude is noble and grand; and the general effect of the whole figure is greatly heightened by the simplicity and elegance of the drapery in which it is clothed.

After this introductory view of the early history of sculpture, we may at once proceed to our illustrations of British art.

The art of sculpture was imported by our Roman conquerors into Britain at a very early period. The remains of Roman and British art in England are well imagined, but executed with so little skill as to admit the conjecture, that the gods and altars, as well as the roads of the time, were executed by the soldiers. The warlike invaders left something like

the love of art behind them when Ætius withdrew his last legion. A brazen statue of king Lud was erected on Ludgate Hill. But the colossal dimensions, and fierce countenance which Bede celebrates, are bad symptoms of the power of the sculptor's art. Amplitude had been taken for sublimity, and gigantic ferocity for heroic grandeur.

The Saxons succeeded the Romans, and whatever they did had a dash of the wildness of that blunt people. Their attempts to imitate the human form are savage and hideous. But riches and repose began to aid them in softening down the barbarous rudeness of imitation; and in their sacred architecture they had begun to display some taste, when their progress was arrested by the Normans, a people as fierce as themselves. To this band of conquering adventurers we owe, among other benefits, the introduction of a better kind of sculpture. The tombs of the days of William the Norman and his sons were good examples of the Gothic taste; and the forms sculptured upon them were stiff but natural, and intelligible though coarse.

Of the state of the fine arts in France during the middle ages, but little is correctly known, but the following beautiful specimen of sculpture, forming the capital of a column executed in the eighth century, evinces considerable skill in the general outline of the figures, as well as in the execution of the drapery.

We introduce this illustration in the present historical view of our own sculpture, as it exactly resembles that which was employed in English ecclesiastical edifices in England about half a century later.

As we pass along the stream of time, the beauty of church architecture increases; and the devout meaning and skilful execution of its accompanying sculptures became more and more remarkable. The return of the Crusaders brought a taste for the Grecian art, which was then visible wherever they had marched. The church became strong, rich, ambitious, and desirous of splendour. Magnificent abbeys were built, and the whole skill and genius of the land were employed in embellishing them with traditions of the saints and legends of the church. In the days of the third Henry, the desire to excel seemed universal, and many works of true genius adorned our cathedrals. For several centuries our demands for sculpture were mostly supplied by foreign hands; and often from a foreign market. The heathen gods, under the protection of modern names, had gained a footing in the island; and a crowd of allegorical creatures came after them. If we examine our cathedrals, where plainness and simplicity should preside, there this marble offspring of affection and idle learning are seated. It is painful to hear sculpture speaking over English dust with an alien tongue. The artists of those days did, however, undertake sometimes to represent nature; but they gave only the lifeless image, they missed the serenity of slumber, and carved the horror of death. If we pass on to a later period, it will be found that the sculpture of the last hundred years has partaken more largely of English feeling and intellect; and, though often deformed by allegory and affectation, debased sometimes by vulgarity and in general unelevated and monotonous, it contains works of a high and pure order. Of some of her domestic monuments in particular England may be justly proud; here the soundness of heart has happily prompted many daring acts of rebellion against the false tendency of professional taste.

Cibber was among the first of our artists who returned to sense and nature, and his statues of raving and melancholy madness, are the earliest of our works after the reformation, which show an original grasp of mind. The cold insult of Pope is forgotten as we look on those "brainless brothers," who yet stand foremost in conception and second in execution among all the productions of English sculpture.

Rysbrach succeeded Cibber, and Sheemaker came and divided with him the public patronage. Though feeble, literal, and languid, they maintained something of the elevation of style which Cibber introduced; produced several recumbent figures which seem nature transcribed rather than nature exalted by art, yet they are nature still, and welcome from that novelty. They were heavy and ungraceful; they had not the skill to use allegory so as to make it understood, or nature so as to render it attractive.

Roubiliac's name still stands deservedly high though it is at this period suffering under something like an eclipse. His ideas are frequently just and natural, and his execution is always careful and delicate. But he sacrificed nature and simplicity for the sake of effect; his works are all too lively and too active. He has little sedate beauty, little tranquil thought. Violent passion can be carved by a commoner hand then men imagine. A broad mark is easily hit: but quiet agony of mind and deep thought are less palpable things that demand the hand of a master. Roubiliac dealt largely in abstract ideas, nor did he use them wisely. We may take his monument of Mrs. Nightingale as an example; it is his most celebrated work, and a work of beauty and pathos—a dying wife and an agonized husband. So far all is natural and consistent. But he could not be satisfied with nature and with simple emotion. He opens an iron door, and sends forth a skeleton; a Death projecting his allegorical dart against the woman, while the man seeks to stay it with a hand of flesh and blood. Can any thing be more absurd than this strange mixture of shadow and substance? See with what discretion Milton has escaped from the dfficulty of describing Death, and yet we feel satisfied with the indistinct image which he gives :—

"What seemed his head
The likeness of a kingly crown had on."

We have no grinning jaws nor marrowless bones here. When blood was first shed on earth, the same great poet makes Death rejoice as a bird of prey smelling coming carnage:

"So scented the grim Feature, and upturn'd
His nostrils huge into the dusky air."

The poet saw the difficulty; ordinary minds see

none; and hence the sculptor has given us an image which startles and disgusts.

Bacon infused more English sense into sculpture than any of his predecessors. Amidst his personifications of cities and countries, and virtues and qualities, and his crowd of chubby boys, large about the middle and long in the wing, there frequently appeared something of a better nature; his happier judgment seemed often on the point of vanquishing allegory, but the dark abstraction always prevailed. Forms which came without the pain of study or the labour of meditation, were made too welcome; he was ambitious of finding a new labour for Hercules, and a christian employment for Minerva.

Bacon's statue of Samuel Johnson is an excellent work: stern, severe, full of surly thought and conscious power: and his Howard has the look of the philanthropist. The limbs, arms and necks of both are naked; but the sentiment overcomes historical inaccuracy.

The bust sculpture of Nollekens is deservedl esteemed. This popular branch of the art, when confined to legislators, warriors, orators, and poets, becomes the handmaid of history; but the calls of vanity bring a thousand heads to the sculptor's chisel, which have no other claim to distinction than what money purchases, while a man of genius contents himself with the fame of his productions, and is either too poor or too careless to confer a marble image of his person to posterity. Nollekens, like Bankes, had the ambition to introduce a purer and more tasteful style of art. His busts, which he considered as the mere small change that enabled him to buy his marble and pay his men, will alone preserve his name.

In Flaxman's mind the wish to work in the classic style of Greece, and the love to work in the original spirit of England, long held an equal war, sometimes forming natural and beautiful unions, and often keeping purely and elegantly asunder. To the aid of his art he brought a loftier and more poetical mind than any of our preceding sculptors; and learning unites with good sense and natural genius in all the works which came from his hand. He has penetrated with a far deeper sense of the majesty of Homer, into the Iliad and Odyssey, than Canova, who dedicated his whole life to the renovation of the antique; nor has he failed to catch the peculiar inspiration of whatever poet his fancy selected for illustration. We feel that he has rarely failed to reflect a true general image of the great original; we see the same grave majesty and the same simplicity, and we own the group at once as the offspring of the spirit of Homer, Æschylus, or Dante. These works have spread the fame of Flaxman far and wide. On the bulk of his works in marble he has impressed the same serene and simple spirit: he always thinks justly, his conceptions are all inspired by strong sense and by the severer part of poetic feeling.

Westmacott has shared largely in public and in private favour, and some of the most expensive of our monuments have been confided to his talents. He has in so far profitted by the wise example of West and the good sense of Flaxman, obeyed the admonition of our cold climate, and respected the blushes of our ladies, and clothed some of his works in the costume of the country. In his Hindoo Girl there is a certain wildness of eye; the stamp of a remote land is upon her: and in his Widowed Mother and Child he has attained the pathos of truth.

The renovation of the statue of Achilles in honour of Wellington and Waterloo surpasses all imaginable absurdity. By what perversity of fancy the cast of an antique figure was thought a fit visible record of English glory, it is impossible to say. The statue of Achilles (if Achilles it be) had already told its story to the world, and it was a strange piece of folly on the part of Mr. Westmacott to press it into the British service; but in our service it cannot abide; remove the inscription, and the Greek is a Greek again. We hardly blame Westmacott for this; it is honourable enough to make money in an honest way, and we are obliged to the hand which extends our acquaintance among works of genius. But who would dedicate a translation of the Iliad as a national trophy to the honour of the heroes of Waterloo?

England may justly be proud of Chantrey; his works reflect back her image as a mirror; he has formed his taste on no style but that of nature, and no works of any age or country but his own can claim back any inspiration which they have lent him. He calls up no shapes from antiquity: he gives us no established visions of the past: the beauty and the manliness which live and move around him are his materials, and he embodies them for the gratification of posterity. He seems to work as if he were unconscious of any other rival but nature. The antique is before him, but he prefers flesh and blood, and it would certainly cost him far more labour to imitate the work of another school, than to create an image from the impulse of his own feeling. Robert Burns said, that the muse of his country found him as Elijah did Elisha, at the plough, and threw her inspiring mantle over him; and the same may be said of Chantrey: it was in a secluded place, a nameless spot, into which art had never penetrated, that the inspiration of sculpture fell upon him.

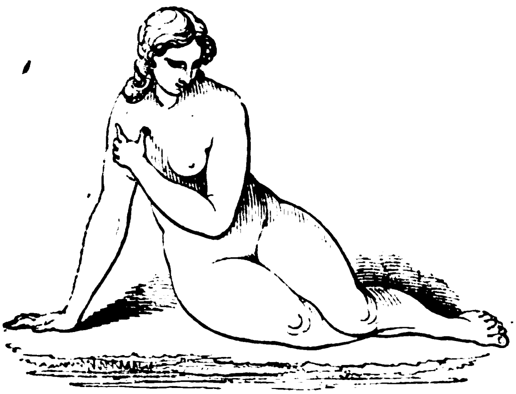
The Greeks charmed the whole earth by working exactly in the same spirit as this great man. But the liberties which they took with their Olympus gave them an advantage over modern sculptors. A Christian artist allows not his fancy to invade the sanctities of heaven—he presumes not to embody its shapes—he dares not define the presence of his Creator. Mr. Chantrey's groups, though the most admired, are not perhaps the happiest of his works.

Of all Mr. Chantrey's busts, perhaps that of the late Sir Walter Scott is the best. The poet possesses a face as changeable and various as the characters he drew in his works, and an expression which nothing but genius something akin to his own can hope to seize. In this remarkable bust the brow is full of thought, the eyes look through the spectator, and there is a grave humour about the mouth which seems ready to escape in speech. The whole face is finished with the most fascinating skill.

We may here observe, that this beautiful bust has been the parent of nearly all those which have appeared about the streets of the metropolis since the death of the above distinguished individual. Chantrey charged two guineas for the plaster cast—the Italians who have moulded it from the original charge half-a-crown.

Bailey studied under Flaxman. His conceptions are in general just, and his workmanship almost always good. His Eve is loveliness personified, and though undraped, yet breathes the purest spirit of chastity. Simple description indeed can hardly do justice to the peculiar beauty, simplicity, and modesty

of this figure, and we find it necessary to call in the aid of our artist's pencil for the purpose of illustrating the work of this highly-talented sculptor.



Of this statute we cannot speak too highly. There is a grace and almost infantine simplicity in the figure which serves to place it in the highest order of sculpture. It is now in the possession of the Bristol Literary and Scientific Institution. Mr. Lough has highly distinguished himself by a variety of figures, which are now exhibiting in his own gallery, and his best group is a masterly representation of Duncan's Horses, which Shakspeare describes as devouring each other, forming one of the portents of the death of their royal master.

Of Mr. Thom, the Scottish sculptor, we had reason to expect much, but since the completion of his figures illustrative of Burns, his career has not at all realized his early promise.

In the present enumeration of sculptors, we must not omit to notice one who has peculiarly distinguished himself by the useful application of his art to the purposes of architecture. Mr. Bubb has established a depôt in Grafton Street, East, in which a material called Lithargelite, is modelled, and converted into figures much superior in point of durability to many sorts of marble. There are more than fifty statues executed by this artist in the Regent's Park, and, amongst other works, we may particularly notice a basso-relievo, about one hundred feet long, for the Italian Opera House. His monument to the memory of Pitt has long been deservedly admired.

In concluding our historical view of modern sculpture, we cannot but turn for a passing glance to Italy. Once leaders in arts, as well as in arms, the Italians are now sadly degenerated, and they have lately lost one who seemed to bid fair to restore to them much of their ancient fame.

Of modern sculptors out of our own country, Canova certainly held the most distinguished rank, and to him we shall therefore more particularly call the reader's attention. Of the early career of this distinguished artist, whose works we shall now have occasion to notice, it may not be amiss to furnish an illustrative anecdote. Canova—like our own children of genius, Lough and Thom—was of humble extraction. He was born in a mud-walled cottage in the little village of Possagno, among the Venetian hills, on the first day of November, in the year 1757. His father died when he was three years old; his mother married again in a few months, and left her son to the charity of his paternal grandfather, Pasino Canova. Antonio was weak in person, and feeble in constitution: this but endeared him the more to his grandmother, Catterina Cecatto, who nursed him with the tenderest care, and sung him ballads of his native hills, infusing a love of poetry into his heart, of which he ever afterwards acknowledged the value. In his tenth year he began to cut stone, and it was his grandfather's wish that he should succeed him as hereditary mason of the village. The weakness of his body and his extreme youth were ill suited for a laborious trade. Old Pasino, who was a man of some intellect, indulged him in modelling of flowers; and in drawing of animals. Such was his success, that, in his twelfth year, he obtained the notice of the noble family of the Falieri, who had a palace in the neighbourhood. As the notice of the great can rarely be purchased but by something like a miracle, a species of miracle is told to account for the good fortune and fame of Canova. A great feast was given by the Falieri, the dinner was set forth, and the guests assembled, when the domestics discovered that a crowning ornament was wanting to complete the beauty of the dessert, and old Pasino tried in vain to invent something suitable. Young Antonio called for butter, and instantly modelled a lion with such skill and effect as excited the astonishment of the guests—the artist was called in, and he came blushing to receive the caresses of the company, and the first applauses of that kind and opulent family. Its head had the sense to see Canova's genius, and the generosity to encourage him. From that moment his fortune was made, and we speedily find him distinguished by the patronage of the great and powerful of his native land.

The first illustration in our plate Arts, *five*, represents a group from the monument to the memory of the Archduchess Christine, of Austria. This beautiful and pathetic composition was executed by Canova, at the desire of her husband.

There are nine figures employed in the entire monument, and we select for our first group the principal series of three figures.

The figures are all of the natural size, and consist of an allegorical figure of Virtue, with two young females bearing torches: Virtue is represented in the form of a young matron of a dignified but melancholy aspect, bearing before her the funeral urn, on which she seems to rest her forehead; she is attired in a rich tunic, and her hair is unbound and spread in a disorderly way over her shoulders. Ascending the steps, which are spread with a rich carpet, she approaches the door of a tomb. The attendant who goes before her has already reached the entrance, where her steps seem for a moment arrested by the awful feelings which the place inspires, but, bending forward, and lowering her torch to illumine the dark abode, she prepares to enter. The other attendant, who is behind, and is seen in profile, has the same simplicity of dress and character; with downcast eyes, and slow and devoted step she follows her celestial conductor: two wreaths of flowers, joined at the top of the urn, serve to connect the two foremost figures, which would separately form a perfect and charming composition.

Our second series from Canova is selected from a basso-relievo, representing Hercules destroying his children with arrows. It is usually known by the name of the "Infuriate," and we cannot do better

ARTS. FINE.

ITALIAN SCULPTURE. – CANOVA.

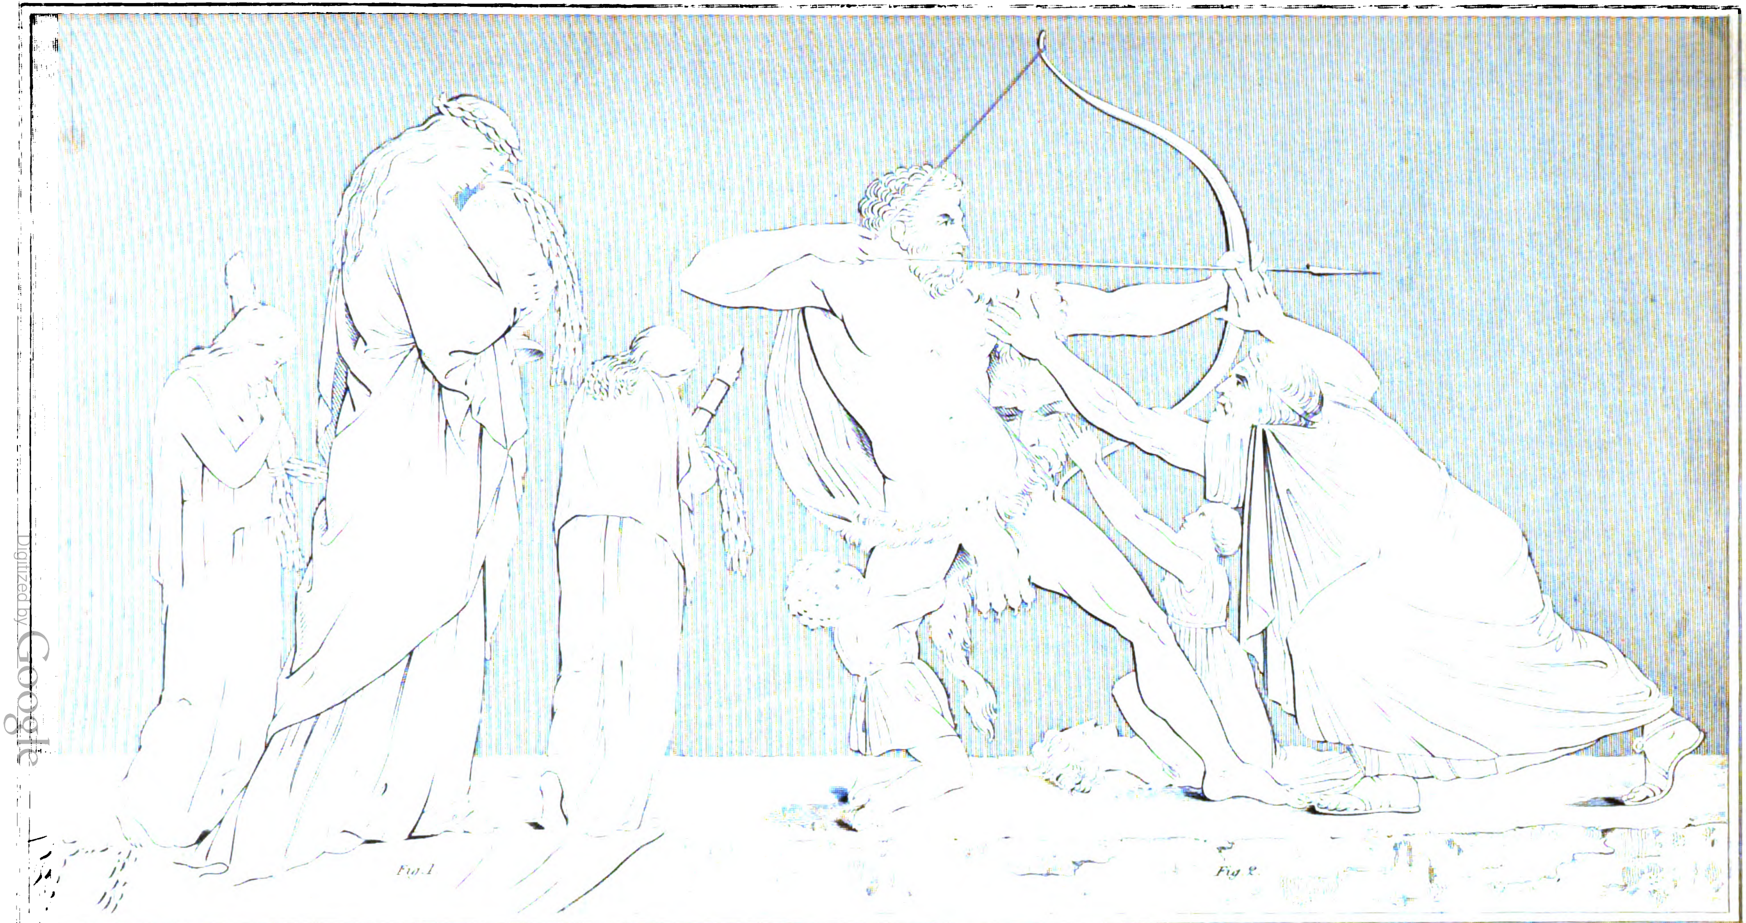


Fig. 1   Fig. 2

London, Published by William Orr, Paternoster Row, Sept.r 29. 1832.

than take the description of the entire work from the pen of the Countess Albrizza, which will enable our readers fully to understand the arrangement of the figures we have selected. (See FINE ARTS, *plate* 1, *fig*. 2.

"The son of Jupiter and Alcmena, after having triumphed over the perils to which the hatred of Juno had exposed him, returned to the bosom of his family, where he found that Lycus, the Theban exile, had forcibly taken possession of his throne, and meditated the destruction of his race. Him the hero slew; but while in the act of purifying himself from the stain of blood, by sacrificing in the temple of Jupiter, the malignant goddess, still pursuing him, caused him to be seized by a sudden frenzy, during which, he destroys his own offspring, believing them to belong to his enemy Euristheus. Canova has pourtrayed this tragical subject with great power and judgment: an altar smoking with the sacrifice, and a pedestal supporting the statue of Jupiter, occupy the centre of the basso-relievo; already the pavement is strewed by the bodies of his children transfixed by arrows, and lying in various attitudes of death. Hercules, still pursuing the work of destruction, is in the act of directing a deadly shaft against one of his infant children whom its unhappy mother has caught up in her arms, and tries to shield with her own body; extending at the same time her hand and arm towards her infuriate husband, with a look of the deepest distraction and moving supplication: she seems to exclaim—'Have pity on thine offspring, thy wife, or thyself;' but in vain,—his insensibility to this appeal, even more than the slaughter which surrounds him, proves the dreadful delusion under which he labours. One child has taken shelter behind its mother, and hiding its face in her vest, seems to think itself secure from the danger which it does not see. Another hides itself behind the altar, and raises its little hand to its ears to deaden the horrid shrieks which fill the temple. A third has seized his father's knee, and, although ignorant of his fault, tries by his piteous cries to stop his fury. A young female is on her knees before him, her hands raised in vehement supplication; and the aged Amphitryon, rushing forward with all the force which age has left him, and neglecting his own safety, places one hand on the breast of Hercules, and endeavours with the other to arrest the murderous shaft.

"Clothed only in his lion's skin, the large and immensely powerful frame of the hero are finely displayed, and fully correspond with the fame of his matchless force; while his distorted features and infuriated aspect show that his mind is darkened by some dire delusion. The relentless goddess, however, unsated even by this slaughter, prepares for herself the deeper vengeance, when, the light of returning reason, shall awaken that terrible and insupportable remorse under which the most wicked of mankind may excite the pity of men and the clemency of Heaven."

This account from the pen of an Italian lady of rank, and high literary acquirements, well describes the powerful conception of Canova, in the work represented in our plate. We have taken the principal figures of the group, the arrangements of the rest will readily be understood.

The Religion of Canova may be said to rank amongst the finest of his works. We shall not here enter into a discussion of the fitness of sculpture for illustrating the highest and holiest of feelings of the human mind, but it is an undoubted fact, and one to which we have alluded elsewhere, that art owes more to the patronage of the clergy than the laity. It was so in ancient Greece and Rome, and is so in the present day.

The splendid statue now before us, which is about twenty-five feet in height, is a sufficient example of what religious enthusiasm will effect when grafted on a high degree of cultivation. On the head of the figure is a tiara, bearing in its front the symbol of the Trinity. The one hand is raised to heaven, while the other rests upon a medallion, on which is sculptured the head of the apostle Peter. We can say but little in praise of this latter portion of the work. The style is purely French. There is a prettiness about it which is but little in accordance with the simple dignity of the principal figure. This fine statue was executed for a temple he proposed to erect at his own birth-place. The previous remark also applies to some of his dancing girls: they are rather the figurante of the French opera, than natural models of classic beauty.

We come now to the *Art of Painting*, and purpose tracing its progress in the same way as we have done its progenitor Sculpture.

We are doubtless indebted to the Greeks for the high state of cultivation which the imitative arts have acquired. In sculpture they attained so high a pitch of excellence, as to remain unrivalled even to the present moment; and it is probable, that as far as relates to the perfect imitation of a single figure, in taste, in expression, and in execution, the same may be said of their painting: but there is much reason to conclude, that in many branches of that art they are surpassed by many artists in the present day.

The practice of the fine arts, so far as it extended to the delineation of certain figures, is of the highest antiquity in Egypt; and, indeed, both the enchorial and sacred writings anciently used in that country, have been supposed to have only changed their forms from actual drawings of visible objects, to those of rude sketches of the same figures, and finally into a running written character, in which the original features were entirely lost. In those papyrus rolls, which are frequently to be found in the coffins of mummies, all these different species of characters are generally employed; and the following group has been reduced from an original fragment of one of those rolls, as affording a perfect idea of the peculiar style of ancient Egyptian art, its chief characteristics being firm decided strokes, simplicity of outline, and only a general indication of the principal features of the object delineated. It will, perhaps, be interesting to mention, that the annexed group probably represents Isis, with her horned head, standing in one of those boats in which the ancient Egyptians supposed the planetary bodies to perform their courses. The accuracy of the original drawing may be relied on, as the roll is in the possession of the Editor.

But in Egypt, the artists appeared to possess no power of selection. When a specific form of character was once adopted, there it remained, and was repeated unchanged for generations. Little action was given to figures, and no attempt at all at expression. Pliny says, that the statues made by the Egyptians in his time, differed in no respect from those made by them 1000 years before. Of their painting, a few figures remain to us; but their date is by no means clear. Two of them, seen at Thebes, and described by Bruce, are supposed by him to be of the time of Sesostris (about 700 years B. C.), who is said to have beautified and restored that city; but this is mere conjecture. Of these paintings, he remarks, that they may be compared with good sign-paintings of his day.

Pliny also speaks of paintings at Ardea, in Italy, older than the foundation of Rome. Unfortunately we cannot follow this author precisely, in his account of the rise of the art in that country any more than in Greece. By his own statement, the only guides he had, except tradition, viz., the Greek authors, were extremely incorrect. But though we may not trust our judgments with him on the origin of painting; yet the view he offered us of its progress, the imperfection of its first essays, the gradual advance towards perfection by the addition of new and more valuable qualities, and the retrograde steps it fell into after it had reached its acme, present an order of things so precisely following the system of nature in every part, that we cannot hesitate to quote his view as given in the *Encyclopædia Britannica.*

After smiling at the claims of the Egyptians, who said that the art had been known and practised in Egypt 6000 years before it was introduced into Greece, he says, that it was not practised in Greece till after the siege of Troy; a circumstance certainly not credible, if the story which he relates of Semiramis be true; and if Homer be correct in imputing so much of sculpture as he does to the artists of that period; or the amusements of Penelope, of Andromache, and of Helen, at their looms, be at all founded in facts. It is not probable that so much of other arts, particularly of weaving coloured designs, should exist, without some advance being made at the only source whence it is natural to imagine they could arise. It is vain to discuss the point; nor is it of much consequence whether it were at Corinth or at Sicyon, that the practice of drawing first attracted particular notice. But, as M. Fuseli has beautifully observed in his first lecture, "if ever legend deserved our belief, the amorous tale of the Corinthian maid, who traced the shadow of her departing lover by the secret lamp, appeals to our sympathy to grant it."

The arts in general, and painting in particular, appear to have been practised in Etruria at a very remote period; and Winckelmann thinks it probable that the Etruscans had made considerable progress in the arts dependent on design, before their communication with Greece. The same inference may be drawn from some passages in the Roman authors, though the evidence of no Etruscan writer on art has been handed down to us. It is probably not without foundation, that the Romans have been accused of having endeavoured to destroy every vestige or monument which they found in the countries they overran, that no traces might be left of the antiquity of the neighbouring nations. This jealousy is in some degree corroborated by the silence of their writers, who appear only to have preserved the names of the vanquished people as triumphal trophies; and not for the purpose of making posterity acquainted with the state of their civilization, or the arts which they had cultivated long before Romulus and his associates came to establish themselves on the banks of the Tiber.

The accompanying vase, which forms part of those excavated by Sir William Hamilton, may be considered as one of the most perfect models of symmetrical outline from the Etruscan school.

Pliny admits, that at Cære, in Etruria, and at

Ardea and Lanuvium, in Latium, there existed in his time some paintings which attracted the admiration of the curious, and which were more ancient than the foundation of Rome. In the third chapter of the 35th book of his *Natural History*, he thus expresses himself: "I cannot contemplate without astonishment those paintings at Cære, which appear recent and fresh after so many ages. The same may be said of the Atalanta and the Helen, which are seen in a ruined temple at Lanuvium. The artist has represented Atalanta naked, and both the figures are of exquisite beauty."

It had long been regretted that the ravages of time and the devastation of Italy had deprived us of every vestige of the paintings of the Etruscans, when the Padre Paciandi, a Theatine monk, discovered near the ancient Tarquinia, formerly belonging to Etruria, several tombs decorated with paintings. He communicated this interesting discovery to the Count de Caylus, in a letter from Rome in 1760, in which he informed him that in the environs of Tarquinia are found a great number of small grots, which had served as tombs, and which were decorated with paintings on the pilastres and friezes.

Winckelmann also speaks of the paintings found in the tombs near Tarquinia; many of the friezes represent combats and assassinations, others appear to relate to the doctrine of the Etruscans on the state of the soul after death.

From the few remains of Etruscan painting which have escaped destruction, it may be inferred that in Etruria, as in every other country, the art was nearly in the same state of rudeness in its infancy; and that at a more advanced epoch, when it began to assume a national feature, it was marked with a similar character to that which was preserved in Tuscany after the revival of the art; that it was more distinguished by grandeur than beauty, and by energy than grace. That this was really the fact, will we think be readily admitted by any person capable of appreciating the accompanying graphic delineation, which for force of expression and poetry of motion is infinitely superior to many designs of the present period.

It was on a vase formerly in the possession of Mr. Hope.

The splendid models of antiquity which are still extant, have left no doubt of the perfection which the art of sculpture had attained, but the more perishable quality of pictures has prevented any direct evidence reaching us with respect to the powers of the Greek artists in painting. We collect from the work on painting of Pliny the elder (which was in a great measure compiled from treatises existing in his time, and from his personal knowledge), that that art had attained an excellence which equalled that of sculpture, and many eminent masters of both are enumerated by him. Phidias, renowned as a sculptor, was also a painter, Apollodorus of Athens is noticed by Pliny as being the first whose painting fixed and absorbed the attention of the spectator, and who discriminated with delicacy the various gradations of shadow in painting, and hence obtained the name of the *shade painter*. Parrhasius, who flourished about the same time, contributed to the advancement of the art by the attention which he paid to the symmetry of the human figure, giving improved expression to the countenance, and carefully finishing the extremities. The greatest painter, however, of ancient times was Zeuxis; whose most celebrated work was the picture of Venus at Crotona, said to have been executed from a selection of five of the fairest virgins of that city. To these must be added, Aristides, Pamphilus of Macedon, Protogenes, and Apelles, who was the painter of Alexander the Great.

The opinions expressed by contemporary authors as to the excellence of these painters, must necessarily be but relative, and can furnish no criterion for a comparison of their performances with the works of modern artists. Much learned controversy has been employed as to the merits and demerits of ancient painting, yet with very few grounds on either side on which to found any arguments. Although not possessed of any paintings of the great Greek masters, surely it may be reasonably inferred that those who had attained such excellence in sculpture, who had discovered the secret of imparting such grace, such nature, such dignity to their statues, and who equally cultivated and admired painting, must also have attained a considerable eminence in that art; their excellence in sculpture may be fairly taken as a key to their standard of taste, with regard to painting. On the other hand, however, it must be confessed that in all probability, they laboured under the great disadvantage, which would necessarily arise from a want of that knowledge of colours, with which chemistry has furnished the modern artist. In addition to this, it can scarcely be doubted that they were ignorant of the practice of painting in oil, although Sir Joshua Reynolds is rather disposed to adopt a contrary opinion.

The only specimens from which we can form any decisive judgment, are the remains which were discovered in Herculaneum and Pompeii, and the frescos or paintings in the baths of Titus. Of the latter it may be observed as a proof of their merit and excellence, that on their discovery, some of them were attributed to Raphael. Although these paintings are unequal to the productions of modern art, both in their colouring and effect, yet some of them are undoubtly of the very first merit in design. But it must be remembered, that they were the work of an age when the arts were already declining; and they cannot be in any degree considered as exhibiting a type of the meridian splendour of the Grecian masters.

Of the paintings found at Pompeii and Herculaneum, it is sufficient to observe that these were small and unimportant country towns, and consequently not likely to possess even what might be regarded as specimens of the best state of the art of the period at which they were executed.

There is every reason to suppose from the minute descriptions of Pliny, Pausanias, and Quintillian, that in the essential parts of invention, expression, grace, and character, the painters of Greece and Rome, rivalled the sculptors; but in the modern invention of grouping, and the union and separation of groups, in the accompaniments of perspective, in beauty of landscape and back ground, and in extreme refinement of colouring, it is probable they were deficient. On these points the descriptions which remain afford no grounds for conclusions. The attempts at back ground in the pictures of Herculaneum are generally puerile, and the most beautiful productions of ancient painting with which we are acquainted, are figures relieved off plain grounds, or rather blended into them.

The fine arts continued to decline with the Roman power, until they were, at last, involved in one common ruin with every thing great and civilized. The history of painting, from the fifth to the eleventh century, is little more than a blank. Still the art was not quite extinct; it existed amidst the terrors of war and bigotry, cherished by the Greek monks in their silent seclusions; and for two centuries, at least, previous to the era commonly assigned to its revival, was practised, though humbly, in fresco and mosaic. With the rise of the Italian republics commences the period at which it assumed a different character; artists were summoned from Greece to adorn the public and private buildings of Florence and Pisa, and Mr. Flaxman states that the mosaic pictures in the interior of St. Mark's at Venice, which was built as early as 1085, are from Greek paintings of the same age. There is little doubt that in some parts of Italy, schools of painting were established as early as the eleventh or twelfth century.

The style of the art at this period is exemplified in the remains which exist; there are in the libraries of the Emperor of Austria and King of France, Greek paintings of great beauty, which were executed in the middle ages; but the finest specimens are to be found in the church of Santa Maria Maggiore, at Florence, which contains the Transfiguration, Resurrection, and Glorification of Christ.

Giovanni Cimabue was born at Florence in 1240, and instructed in the ordinary practice of the Greek artists of the day. But he soon outstripped his masters; and the almost divine honours which he received from his fellow-citizens for a picture of the Virgin, encouraged him to pursue the art with ardour. His pupil Giotto, to whom the world is indebted for the portraits of Dante, Brunetti, and other men of eminence of that period, contributed still further to the advancement of painting, by returning to nature as the standard by which to regulate the actions and expressions of his figures.

After the lapse of nearly one hundred years from the death of Giotto, Tomaso da San Giovanni, better known by the name of Masaccio (from his total neglect of personal appearance), exhibited a more elevated taste, and a grander style of execution than his contemporaries. The art under his hands may be said to have advanced from the weakness of infancy to the station of youth, verging towards the vigour of perfect manhood. He was the first to compose with an eye to the effect of a whole picture. He managed his groups and single figures upon the principles of perspective, which had been taught him by the sculptor Brunelleschi; and by understanding the effect of those principles, first placed the feet of upright figures truly flat upon the ground, and foreshortened his heads and figures with truth and effect. In fact, it was to him future artists were indebted for a more sure and full direction of the line in which the art ought to be pursued. He studied nature with the greatest attention, gave breadth and simplicity to his draperies; and most admirable action, character, and expression to his figures, which are justly and appropriately employed. Even Raphael did not scruple, eighty years afterwards, to study, and sometimes to adopt, his actions; of which there is an extraordinary instance in the figure of St. Paul preaching at Athens. Michael Angelo is also reported by Vasari to have regarded his pictures with great respect and attention. His principal works in the chapel of the Brancacci, in the Church del Carmine, at Florence, became the school of study for all those excellent artists who succeeded him; till at length Leonardo da Vinci, born near that city in 1445, two years after the death of Masaccio, came forth with superior lustre, and eclipsed all that had preceded. Endowed with uncommon genius, all arts and sciences seemed scarely to offer a sufficient field for the exertion of his talents. He grasped at all, and succeeded in whatever he undertook; but by his versatility wasted much of his time in experiment. Had he persevered with steadiness in pursuit of the art of painting, he probably would have carried it to the utmost perfection. As it was, whatever he painted came from his hand elevated and adorned by the pencil of the artist, and presented a complete originality of effect. To truth and precision of character, and whatever had been well done by Masaccio, Leonardo added new and most valuable qualities, by introducing the principles of chiaro-scuro, and depth of tone in colour. By the former of these, pictures were relieved from the tameness of mere imitation, and acquired an increase of power in boldness and strength of relief, and force of effect. Michael Angelo in design, Corregio in finish and chiaro-scuro, and Rubens in composition, are surely indebted to Da Vinci for the foundation of much of their excellence as artists.

A history of the ancient schools of painting is nothing more than a history of the painters who founded them. Michael Angelo and Raphael have the foremost claim to our attention; and we cannot do better than furnish our readers with the masterly contrast of these eminent painters, given by Sir Joshua Reynolds:—"If we put those great artists," says he, "in a light of comparison with each other, Raphael had more taste and fancy, Michael Angelo more genius and imagination. The one excelled in beauty, the other in energy. Michael Angelo has more of the poetical in operation; his ideas are vast and sublime; his people are a superior order of beings; there is nothing about them, nothing in the air of their actions, or their attitudes, or the style and cast of their limbs or features, that puts us in mind of their belonging to our species. Raphael's imagination is not so elevated; his figures are not so much disjointed from our own diminutive race of beings, though his ideas are chaste, noble, and of great conformity to their subjects. Michael Angelo's works have a strong, peculiar, and marked character; they seem to proceed from his own mind entirely; and that mind so rich and abundant, that he never needed, or seemed to disdain, to look abroad for foreign help.

Raphael's materials are generally borrowed, though the noble structure is his own. The excellency of this extraordinary man lay in the propriety, beauty, and majesty of his characters; his judicious contrivance of composition, correctness of drawing, purity of taste, and the skilful accommodation of other men's conceptions to his own purpose."

A taste for the fine arts appears to have been experienced in Germany early in the fifteenth century, though it made but little progress for half a century. At that time Albert Durer relieved it from little better than obscurity by his ingenuity, his fertile invention, and his skilful attention to minute imitation of individual forms. He carefully studied the human figure, but wasted his time in fanciful schemes for regulating proportion, and never attained any very high rank as an artist. The bane of his style, if it may be so called, is meagreness and poverty of forms, mean expression, and capricious and often vulgar invention. Lucas Van Leyden was the best of those who attempted to rival the name of Albert Durer, unless we except Holbein; who, though he never equalled him in composition, infinitely surpassed him in portraiture. The taste of the Germans totally changed after they possessed the knowledge of the works of Michael Angelo.

The history of the art in the neighbouring countries of Flanders and Holland, is merely the same with that of its progress in Germany, till about the middle of the sixteenth century. The extreme richness of colouring which had been effected by John Van Eyck, was maintained entire; and seems almost exclusively to have occupied the attention of the Flemish artists. Their distance from Italy, and the consequent want of intercourse with that country, precluded any precise acquaintance with the peculiar beauties of ancient art; and having no model to guide them, or rival to contend with, they were at liberty to follow the suggestions of their own inclinations. It conducted them to as precise an imitation of the effects of natural objects immediately presented to their eyes as lay in their power. The established religion here, as in Italy, found occupation for the artists in a considerable degree; but its exercise soon deviated into common life, and reached its ultimatum in the days of Rubens and Rembrandt. The former of these "meteors of the art," shining in a sphere completely his own, irradiated the world with a brilliant and uncommon lustre. Possessed of a mind as full of genius as energy, he appears without difficulty to have embraced from contemporary artists, and the great masters of Italy, whose works he visited, those elements of which he composed his own system; the principal features of which are an union of the splendours of the Venetian school, with a grandeur of outline drawn from the Florentine, without its correctness.

So very little is known of what occurred concerning the art of painting in this country, previous to the time when Henry VIII. encouraged the abilities of Holbein in portraiture, and invited Titian to come here, that it would be useless to endeavour to trace its history. Enough, however, is known to satisfy us that it was at a very low standard. It was but little before his time that the people of England began to throw off the yoke of ignorance and barbarism, and to cultivate literature and science. The ambition of Henry to be renowned, and his spirit of rivalry to his great neighbour, Francis I. of France, were quite sufficient motives to stimulate him to the proud aim of becoming a patron of the liberal arts; had not his theological discussions with Luther, and afterwards his more sublunary quarrel with the Pope, so powerfully diverted his attention from them, and produced him so active an employment in deciding the course of the reformation in religion which consequently ensued.

Charles I. endeavoured to introduce a feeling for the art, which had previously been wanting in this country; but for which he appears to have had a very great affection. He employed Rubens during his short residence here, as envoy from the king of Spain, to paint the ceiling of the banquetting room, now the chapel of Whitehall; and procured a treasure of inestimable value to the country by the countenance and encouragement he afforded to Vandyke; and also to other ingenious foreigners who have enriched the country with their productions. He formed a very considerable collection of pictures, in addition to those already possessed by the crown, and at the suggestion of Rubens bought the Cartoons; he employed an artist to copy the works of Titian in Spain, and purchased the cabinet of the Duke of Mantua, at the cost of twenty thousand pounds, and some valuable pictures were sent him as presents. The whole was sold and dispersed by the parliament in 1643, who gave especial orders "that all pictures which had the representation of the Saviour or the Virgin Mary in them, should be burnt." After the restoration many of them were returned to the royal collection, but only to meet utter annihilation by the fire which consumed the palace of Whitehall.

Of those who have practised in this branch of the art, and are departed, Reynolds, Romney, Opie, Barry, Fuseli, and Lawrance, require to be particularly mentioned. The former, with all the splendour of chiaro-scuro and colour, which no one since Rembrandt has wielded with so much power, exhibited in his pictures of Hercules strangling the Serpents, Macbeth, Cardinal Beaufort, and Ugolino, a fund of historic power. Romney also had poetic imagination, feeling, and expression; and in the little leisure allowed by his general practice of portraiture, indulged in the delights ideal subjects afforded him; while Opie presented "images new and striking, drawn directly from nature," and "what he wanted of academical or classical information, he compensated for, in a great measure, by character, by force, and by a just and bold imitation." Barry regularly educated himself for the practice of art, and undoubtedly had the highest and most enthusiastic feeling for its best qualities. With a generons zeal worthy of the highest encomium, he broke entirely from all consideration of the ordinary style of subject or design; and contemplating his art in the most elevated manner, attempted to embody the poetical ideas he entertained. His most sincere admirers must, however, regret that those excellent sentiments, which he so ably inculcated by his pen, were not more completely supported by his pencil.

We have visited the Society of Arts, which are said to contain some of his highest productions, and the reader may judge of our surprise when we beheld Dr. Burney floating in the "Triumph of the Thames," in a bag-wig and gown. Barry was too eccentric in his habits to be a wise man. He was vain, and assumed a peculiarity of feeling to excite an interest, which his merit, as a painter, would otherwise have ensured him.

The names of Fuseli and Lawrance are too fresh in our memories to excite any other than feelings of pain for their loss.

The first of these distinguished artists excelled in the sublime, though it was a species of sublimity which often approached to extravagance. There was a great similarity between Blake and Fuseli; and though the latter had more knowledge as a painter, he was equalled in poetry of conception by the amiable and fervent-minded Blake. The errors of Fuseli arose from the same energy of character which produced his greatest beauties, and this is proved by his own frequent and impassioned declaration, that he would sooner be the author of the forced and capricious style of Gottyius and Spranger, than of the in-insipid taste, to use his own phrase, of Albert Durer. Now the merits of Albert Durer have been examined in the early part of this article.

Last, though not least in the list of eminent artists who have passed from us, we must place the name of Lawrance; the greatest master of portraiture which this or any other country has known. His works form the pride and ornament of every court in Europe, and sovereigns contended for the honour of a sitting. The likenesses of Lawrance were as near to perfection as refined painting can be said to permit, and rarely did he fail to impart to his portraits the refinements of his own mind. To coin a phrase, they were *nature idealized*. In his female portraits—the great test of talent—he had infinitely more grace and variety than Vandyke, or any who preceded him; and Fuseli was often heard to declare, that his female eyes were better than those of Titian. As a curious item in art, and as an indication how his labours were appreciated by the great and powerful, it may be enough to say that he had more orders than he could execute, at prices varying from *two* to seven hundred guineas for each picture.

The art of painting in water colours springing from British soil, and fostered by native talent, ought to be viewed by our countrymen with redoubled interest, from its commencement by Sandby, during its rapid progress, to its ultimate success, aided by the brilliant powers of a Girtin, a Turner, a Prout, a Cattermole, or a Robson.

A confined sphere has been fallaciously urged against this beautiful branch of art; but the "Rembrandt in his Study," of Stephanoff, the "Ann Page and Slender," of Richter, the marine subjects of Fielding, the glowing landscapes of Robson, the picturesque magnificence of Prout, and the domestic beauties of Sharpe, prove the great range of which it is capable; and our increased knowledge of the properties and manufacture of colours affords a reasonable hope of overcoming the perishable nature of those in early use.

The first period at which we hear of water colour painting is about 1710, but the names of Chatelain, Pillement, and their contemporaries fade before the greater genius of Paul Sandby, who was born at Nottingham, in 1732. While studying in the drawing school in the Tower, at the age of fourteen, he gave such indications of future talent, that in 1748 he accompanied General Watson, as draughtsman, through the highlands of Scotland, and etchings from his sketches made during the tour, attracted much observation. The best productions of his pencil are yet rarely surpassed for spirit, clearness, and transparency.

John Cozens excelled in wild and romantic scenery, but his works are little more than tinted chiaro-scuro, and he terminated a life, of which little is known, in a state of mental derangement in 1799.

Michael Angelo Rooker, R. A., was educated as an engraver by his father, and subsequently became a pupil of Paul Sandby; his most noted works are the views painted to illustrate the series of Oxford Almanacs; and his large collection of drawings after his death, which took place March 3, 1801, brought about £1,240.

A new and brilliant era in this school, hitherto holding an uncertain and dubious rank, sprung up under the auspices of Thomas Girtin, who, when his talents for painting first developed themselves, assiduously studied nature; to his tour in Scotland, with his early patron Mr. Moore, may doubtless be attributed the wildness of imagery and general boldness which stamps with pre-eminence the finest productions of this master.

Nothing could exceed the grandeur and originality of his conception, but a want of drawing is frequently observable in many of his paintings, and he is supposed to have been tempted to work with less regard to correctness of form, in proportion to the ease with which he produced depth and richness of colour, and to have become at length so enamoured of colouring and effect, as to consider drawing of little consequence to the character of a picture.

But that vicious course which makes a wreck of the body, cannot fail to ruin the mind; the continued sensual indulgence of this extraordinary man enfeebled his mental powers, and the distinguished competitor of Turner, the thoughtless, kind-hearted Girtin, by a premature death in 1802, perhaps but saved his posthumous fame from the imputation of sinking into a mannerist.

About 1804, the conversation among many eminent artists frequently turned upon the injury their works sustained in the exhibition rooms of the Royal Academy, being often hung in bad light from insufficiency of space. The academicians were sensible of the unfitness of their rooms, for the purposes to which, from necessity alone, they were appropriated; they had no space to build on, and the evil was without remedy.

To these circumstances the Society of Painters in Water Colours owes its origin; and the first exhibition was opened in Brook Street, Grosvenor Square, to which the Royal Academicians were the foremost in crowding, and unanimous in wishing that success to the undertaking with which it has been crowned, from its first opening on the 22d of April 1804, to its present annual exhibition, in Pall Mall, East.

In concluding this article, it may be proper to state, that we have confined ourselves as closely as possible to an historical and critical view of the Fine Arts. The *practice* of painting, sculpture, engraving, modelling and casting will be found under those several heads.

Arts, *Useful*. See Manufactures and Commerce.

Arundel Oil; this name has been given to a powerful purgative medicine, extracted from a nut growing in the East Indies.

Arundelian Marbles; ancient marbles illustrative of the history and mythology of the Greeks. They are so called from the Earl of Arundel, by whom they were conveyed from Paros into England.

They contain the principal epochs in the Athenian history, from the first year of Cecrops, 1582 years B. C., to 354 years B. C.

ARUNDO; the reed or instrument which separates the threads of the warp.

ARX; the ancient name for the citadel of a fortified town.

ARYTÆNO EPIGLOTTI; fleshy fasiculæ attached to the arytænoides and the epiglottis.

ARYTÆNOIDES, in *Anatomy*, two cartilages forming the head of the larynx.

ARYTHMUS, in *Music*, the modulation of time.

AS. The Romans used this word in three different ways, viz., to denote, 1, any unit whatever, considered as divisible; 2, the unit of weight, or the pound (*libra*); 3, their most ancient coin. In the first use of the word, the pound, foot, *jugerum sextarius*, were called *as*, when contradistinguished from their divisions or fractions. In fact, the word was applied to any integer, as, inheritances, interest, houses, funds, &c. Therefore *ex asse heres* signifies *to inherit the whole*. Different names were given to different numbers of *asses: dupondius (duo pondo)* = 2 *asses, sestertius (sesqui tertius*, viz., the third half = 2½ *asses tressis* = 3 *asses, quatrussis* = 4 *asses*, and so on to *centassis* = 100 *asses*. The *as*, whatever unit it represented, was divided into 12 parts or *ounces (unciæ)*, and the different fractions of the *as* received different names, as follows:—

As	12 ounces.	Quincunx . .	5 ounces.
Deunx . . .	11 ..	Triens	4 ..
Dextans . .	10 ..	Quadrans, or teruncius .	3 ..
Dodrans . .	9 ..	Sextans . . .	2 ..
Bes, or des .	8 ..	Uncia	1 ounce.
Sextunx . .	7 ..		
Semis . . .	6 ..		

Sescuncia was 1½ ounce.

1 uncia contained 2 semiunciæ
3 duellæ
4 sicilici
6 sextulæ
24 scrupula (scriptula, or scripula,)
48 oboli
144 siliquæ.

Scholars are not agreed on the weight of a Roman pound, but it is not far from 327.1873 *grammes*, French measure. Budæus has written 9 books *De Asse et ejus Partibus* (Of the As and its Parts). In the most ancient times of Rome, the copper coin, which was called *as*, actually weighed an as, or a pound, but, in different periods of the republic and the succeeding empire, this coin was of very different values.

ASAPHATUM; a sort of serpigo, supposed to be generated in the pores like worms.

ASAPHEIS; defective utterance.

ASARITES, in the ancient pharmacopœia, implied a diuretic wine.

ASAR; a Persian gold coin, worth about six shillings.

ASBESTINUM; a cloth or paper made from the mineral called asbestus.

ASCENDANT, in *Astrology*, any heavenly body supposed to preside over the fate of an individual.

ASCENDANT; an ornament in masonry and joiner's work, which borders the three sides of doors, windows, and chimneys.

ASCENDING, in *Astronomy*, is said of such stars as are rising above the horizon in any parallel of the equator; and thus, likewise, *ascending latitude*—the latitude of a planet when going towards the north pole. *Ascending node* is that point of a planet's orbit, wherein it passes the ecliptic to proceed northward. This is otherwise called the *northern node*.

ASCENDING, in *Anatomy*, is employed to describe that part of the aorta from the point where it leaves the heart to its point of curvature.

ASCENDING VESSELS, in *Anatomy*, those tubes which carry the blood upwards.

ASCENSION, in *Astronomy*. We understand by the *right ascension* of a star, that degree of the equator, reckoned from the beginning of Aries, which comes to the meridian with the star. By the right ascension and declination, the situation of stars in the heavens is determined, as that of places on the earth by longitude and latitude. By *oblique ascension*, we understand that degree of the equator, counted as before, which rises with the star, in an oblique sphere.

ASCENSIONAL DIFFERENCE, is the difference between the right and oblique ascension of the same point in the sphere. It is sometimes used to describe the space of time the sun rises or sets before or after six o'clock.

ASCENSUS MORBI; the ascent or increase of a disease.

ASCENT OF BODIES. See MECHANICS and ATTRACTION.

ASCIA, in *Anatomy*, a bandage in the form of an axe.

ASCIA; inhabitants of the globe having no shadow, such as those in the torrid zone, who twice a year have their sun at noon in the zenith.

ASCITES; dropsy in the region of the abdomen.

ASE. This term, which is now obsolete, was employed to describe a loathing of food, arising from a diseased stomach.

ASELLI; two stars of the fourth magnitude.

ASEPTA, in *Chemistry*, means a body which has not undergone the putrefactive process.

ASHALTUM. See ASPHALTUM and BITUMEN.

ASHES; the fixed residuum, of a whitish or whitish-grey colour, which remains after the entire combustion of organic bodies, and is no longer able to support combustion. The constituent parts of ashes are different according to the different bodies from which they originate. The ashes of vegetables consist chiefly of earthy and saline ingredients, the latter of which may be separated by washing, and are called *vegetable alkali*. (See ALKALI.) The more compact is the texture of the wood, the more alkali it affords. Some herbs, however, yield more than trees, and the branching fern the most. The more the plants have been dried, the less they produce. The vegetable alkali is always combined with carbonic acid. The greater, therefore, the heat by which the ashes are produced, and the more continued and powerful the calcination of the alkali, the more caustic will it be. It can only be entirely purified from foreign substances by crystallization. (See POTASH.) Of quite a contrary quality are animal ashes, particularly those obtained from bone. After calcination, it retains its original texture, and contains besides lime a peculiar acid, called *phosphoric acid*. The use of vegetable ashes is very extensive, as is well known; soapmakers, bleachers, and other tradesmen use them in

an immense quantity. They are also an excellent manure.

Ash-Pit; that part of a furnace intended to receive the waste fuel.

Ashlar Work; flat stones employed for facing buildings, &c.

Ashler Timbers; wooden beams used to support the roof of a building.

Asiti; an epithet for those abstaining from food.

Asinesia, in *Medicine*, the state of apoplexy or palsy.

Aslani; the Turkish name for a Dutch dollar.

Asmaga; the mixing of a fusible alloy of metal.

Aspalathus; a powerful aromatic occasionally employed in pharmaceutical preparations.

Asparagiu; the fluid extract from asparagus.

Aspasia; a constrictive medicine for the pudenda muliebria.

Aspect, in *Astronomy* and *Astrology*, denotes the situation of the planets and stars with respect to each other. There are five different aspects:—1, sextile aspect, when the planets or stars are 60° distant, and marked thus ⚹; 2, the quartile or quadrate, when they are 90° distant, marked □; 3, trine, when 120° distant, marked △; 4, opposition, when 180° distant, marked ☍; and 5, conjunction, when both are in the same degree, marked ☌. Kepler added 8 more. It is to be observed, that these aspects being first introduced by astrologers were distinguished into *benign*, *malignant*, and *indifferent;* and Kepler's definition of *aspect*, in consequence is, "*Aspect* is the angle formed by the rays of two stars meeting on the earth, whereby their good or bad influence is measured."

Aspect Double. See Optics.

Asper; a Turkish coin equal to three farthings of our money.

Aspera Arteria; the windpipe, so called from the inequality of its cartilages.

Asperginee; medicines administered by external sprinkling.

Asphalitis; the last vertebræ of the loins.

Asphaltum; a soft bituminous pitch found in many parts of the world, but more especially on the banks of the Dead Sea.

Asphyxia; the state of a living man in whom no pulsation can be perceived. It begins with an inactivity of the lungs, which proceeds to the heart and brain. The person appears dead, without breath, pulsation, or feeling. It may be occasioned by different causes, either such as interrupt the mechanical motion of breathing, or such as disturb the action of the lungs themselves. The former may be caused by an external pressure on the breast, if air enters the thorax through wounds, or by an accumulation of blood in the lungs, so that they cannot contract themselves: the latter state takes place if no air at all enters the lungs, as is the case with suffocated, drowned, or hanged persons, or if the air breathed in cannot support life.

Aspiny; a medicinal drug formerly exported in large quantities from Lyons, but now little employed.

Ass; a charge in heraldic coats of arms, where it was the emblem of patience.

Assac, in *Chemistry*, the same as girmini ammoniacum.

Assafœtida; a drug brought from Persia, and occasionally employed in medicine.

Assai; a musical term which indicates that the time must be accelerated or retarded, as *allegro*, quick; *allegro assai*, still quicker; *adagio assai*, still slower.

Assanegi; the powder that falls off from the walls of salt in the salt mines.

Assanus; a weight among the ancients, amounting to two drachms.

Assaron; another name for the measure called in the Scriptures omar.

Assatura; a term descriptive of the poisonous effects ascribed to fresh cooked meat.

Assault, in military affairs, implies the moment of advance, when the attacking party throwing off the protection of their intrenchments, advance single-handed to the combat.

Assay, the metallurgical result of the process of assaying, which see.

Assay-Balance. See Balance.

Assaying, a species of chemical analysis, to ascertain the quantity of gold or silver in a metallic alloy. In its more extended meaning, and in the sense in which we shall adopt it in the following article, it is used for the determination of the quantity of metal in connection with any other mineral employed for practical purposes. The assaying of ores may be performed either by what is termed the dry or moist processes; the first is the most ancient, and, in many respects, the most advantageous, and as such still continues to be generally used.

Assays are made either in crucibles with the blast of the bellows, or in tests under a muffle. The assay weights are usually imaginary, sometimes an ounce represents an hundred weight on the large scale, and is subdivided into the same number of parts, as that hundred weight is in the great; so that the contents of the ore obtained by the assay, shall accurately determine by such relative proportion, the quantity to be expected from any weight of the ore on a larger scale. In selecting the ores, care should be taken to have small portions from different specimens, which should be pulverized, and well mixed in a metal mortar. The proper quantity of the ore is then taken, and if it contain either sulphur or arsenic, it is put into a crucible or test, and exposed to a moderate degree of heat, till no vapour arises from it; to assist this volatilization, a small quantity of powdered charcoal is sometimes added.

To assist the fusion of the ores, and to convert the extraneous matters connected with them into scoria, assayers use different kinds of fluxes. The most usual and efficacious materials for the composition of these are, borax, tartar, nitre, sal ammoniac, common salt, glass, fluor-spar, charcoal powder, pitch, lime, litharge, &c. in different proportions. We may here more particularly mention two or three fluxes. The white flux consists of 1 part of nitre, and 2 of tartar, well mixed together.

The Cornish reducing flux consists of 10 oz. of tarter, 3 oz. and 6 drachms of nitre, and 3 oz. and 1 drachm of borax, mixed well together. These answer every purpose, provided the ores be deprived of all their sulphur; or, if they contain much earthy matters, because, in the latter case, they unite with them, and convert them into thin glass: but if any quantity of sulphur remain, these fluxes unite with it, and form a compound, which has the power of destroying a portion of each of the metals; consequently, the assay under such circumstances must be very inaccurate. The principal difficulty in assaying appears to be in the appropriation of the proper

fluxes to each particular ore, the successful performance of which requires a degree of knowledge that can only be attained by an extensive practice.

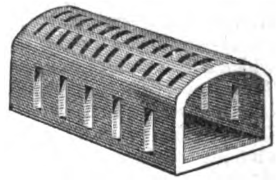
The late celebrated Bergman first suggested the moist process for assaying. It depends upon a knowledge of the chemical affinities of different bodies for each other; and must be varied according to the nature of the ore; it is very extensive in its application, and requires great patience and address in its execution. To enable our readers to understand the process of assaying generally, it may be advisable to furnish a more particular account of both methods.

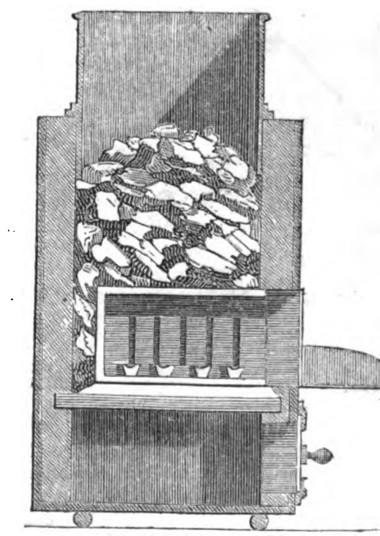
We may commence by pointing out the process for assaying copper ores. The experimentalist should take an exact troy ounce of the ore, previously pulverized, and calcine it thoroughly; stirring it all the time with an iron rod, without removing it from the crucible; after the calcination, an equal quantity of borax must be added, half the quantity of fusible glass, one-fourth the quantity of pitch, and a little pounded charcoal. Cover the mass with common salt, and put a lid on the crucible, which is to be placed in a furnace: the fire is to be raised gradually, till it burns brightly, and the crucible continued in it for half an hour, stirring the metal frequently with an iron rod, and when the scoria which adheres to the rod appears clear, then the crucible must be taken out, and suffered to cool; after which it must be broken, and the regulus separated and weighed; this is called black copper, to refine which, equal parts of common salt and nitre are to be well mixed together. The black copper is brought into fusion, and a teaspoonful of the flux is thrown upon it, which is repeated three or four times, when the metal is poured into an ingot mould, and the button is found to be fine copper.

We may now point out how the process should be performed in the humid way. Make a solution of vitreous copper ore, in 5 times its weight of sulphuric acid, and boil it to dryness; add as much water as will dissolve the sulphate of copper thus formed; in this solution place a clean bar of iron, which will precipitate the whole of the copper in its metallic form. If the solution be contaminated with impure iron, the copper must be re-dissolved in the same manner, and precipitated again.

We come now to the precious metals, which will require a more particular illustration. The experimentalist must take the assay quantity of the ore finely powdered, and after roasting it well, add to the residuum about double the quantity of granulated lead. It must then be put in a covered crucible, and placed in a furnace; raise the fire gently at first, and continue to increase it gradually, till the metal begins to work: if it should appear too thick, make it thinner by the addition of a little more lead; if the metal is too rapidly excited, the fire should be diminished. The surface will be covered by degrees with a mass of scoria, at which time the metal should be carefully stirrred with an iron hook heated, especially towards the border, lest any of the ore should remain undissolved; and if what is adherent to the hook when raised from the crucible, melts quickly again, and the extremity of the hook, after it has become cold, is covered with a thin, shining, smooth crust, the scorification is perfect; but, on the contrary, if while stirring it, any considerable clamminess is perceived in the scoria, and when it adheres to the hook, though red hot, and appears unequally tinged, and seems dusty or rough, with grains interspersed here and there, the scorification is incomplete; in consequence of which, the fire should be increased, and what adheres to the hook should be gently shaken off and returned with a small ladle into the crucible again. When the scorification is perfect, the metal should be poured into a cone, previously rubbed with a little tallow, and when it becomes cold, the scoria may be separated by a few strokes of a hammer. The button is the produce of the assay.

To perform the same process by cupellation, take the assay quantity of ore, roast and grind it with an equal portion of litharge, divide it into 2 or 3 parts, and wrap each up in a small piece of paper; put a cupel previously seasoned under a muffle, of which a representation is given in the accompanying figure, with about 6 times the quantity of lead upon it. When the lead begins to work, carefully put one of the papers upon it, and after this is absorbed, put on a second, and so on till the whole quantity is introduced; then raise the fire, and as the scoria is formed, it will be taken up by the cupel, and at last the silver will remain alone. This will be the produce of the assay, unless the lead contains a small portion of silver, which may be discovered by putting an equal quantity of the same lead on another cupel, and working it off at the same time; if any silver be produced, it must be deducted from the assay. This is called the "witness." The common sort of furnace in which the assay is carried on, is shown in the cut beneath. The muffle and cupels are seen beneath the fuel.





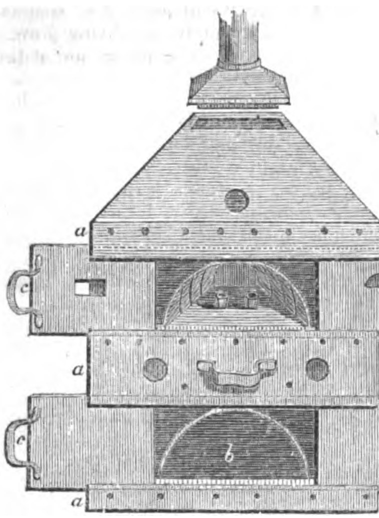
To effect the same thing in the humid way, boil the silver ore in dilute nitrous acid, using about 25 times its weight, until the sulphur is quite exhausted. The silver may be precipitated from the solution by muriatic acid, or common salt. Fixed alkalies precipitate the earthy matters, and the prussiate of

potassa will show if any other metal be contained in the solution.

The general method of examining the purity of silver, is, as we have already seen, by mixing it with a quantity of lead proportionate to the supposed quantity of alloy; by testing this mixture, and afterwards weighing the remaining button of silver. This is the same process as refining silver by cupellation.

It is supposed that the mass of silver to be examined consists of 12 equal parts, called penny-weights; so that if an ingot weighs an ounce, each of the parts will be 1-12th of an ounce; hence, if the mass of silver be pure, it is called silver of 12 penny-weights; if it contains 1-12th of its weight of alloy, it is called silver of 11 penny-weights; if 2-12ths of its weight be alloy, it is called silver of 10 penny-weights, which parts of pure silver are called 5 penny-weights. It must be observed here, that assayers give the name penny-weight, to a weight equal to 24 real grains, which must not be confounded with their ideal weights. The assayers' grains are called fine grains. An ingot of fine silver, or silver of 12 penny-weights, contains then 288 fine grains; if this ingot contain 1-288th of alloy, it is said to be silver of 11 penny-weights and 23 grains; if it contain 4-288ths of alloy, it is said to be 11 penny-weights, 20 grains, &c. Now a certain real weight must be taken to represent the assay-weights: for instance, 36 real grains represent 12 fine penny-weights; this is subdivided into a sufficient number of other smaller weights, which also represent fractions of fine penny-weights and grains.

We have already shown the form of the common furnace, but think it advisable to add a view of another of more general application.



The construction of this very useful furnace is simple, and will readily be understood. Its form is square, terminating in a truncated pyramid. The doors should be provided with handles of some non-conducting material, and the semi-circular apertures shown in the figure are found useful. The fuel is put in at the top.

We may in conclusion notice the mode of assaying ores and earths containing gold. That which is now most generally used is by amalgamation; the proper quantity is taken and reduced to a powder, about 1-10th of its weight of pure mercury is added, and the whole triturated in an iron mortar. The attraction subsisting between the gold and mercury quickly unites them in the form of an amalgam, which is pressed through chamois leather; the gold is easily separated from this amalgam by exposure to a proper degree of heat, which evaporates the mercury and leaves the gold. This evaporation should be made in a furnace with a current of air ascending a pipe in which the mercury is condensed.

This is the foundation of all the operations by which gold is obtained from the rich mines of Peru, Mexico, and other parts of South America.

Assembly, in military operations, the second beat of the drum before the march.

Assers, in *Architecture*, laths which support the tiles of the roof, in imitation of which the dentils were made.

Assident Signs; symptoms which occasionally attend any disease to which the human frame is incident.

Assignable Magnitude; any finite magnitude.

Assignable Ratio; the ratio of finite quantities.

Assignat; the name of the national paper currency in the time of the French revolution. Four hundred millions of this paper money were first struck off by the constituent assembly, with the approbation of the king, April 19, 1790, to be redeemed with the proceeds of the sale of the confiscated goods of the church. August 27, of the same year, Mirabeau urged the issuing of 2000 millions of new assignats, which caused a dispute in the assembly. Vergasse and Dupont particularly distinguished themselves as the opponents of Mirabeau. They saw that the plan was an invention of Clavière (of whose work the speech of Mirabeau was only an extract), to enrich himself and his adherents; that it would tend to put the rich usurers in possession of the wealth of the nation, which would be insufficient to redeem the assignats, particularly if they were increased. Among other arguments, Mirabeau maintained the expediency of the measure he proposed, on the ground that the holders of assignats would necessarily support the new constitution, which was the only guarantee for the redemption of the assignats. His exertions were seconded by Pethion, and 800 millions more were issued. They were increased by degrees to 40,000 millions, and the currency after a while became of no value. It was a common thing to employ this species of paper money as a lining for rooms.

Assimilation, in *Medicine*, an action by which the nourishment assimilates with the thing nourished. It differs only in name from nutrition. See Aliment and Absorbent.

Assis, in the Egyptian pharmacopœia, a pill prepared from hemp leaves.

Assis, in *Heraldry*, sejant, or sitting, as a lion assis affronté, or sejant gardant affronté.

Assistentes, the prostrate glands; so called because they lie near the bladder.

Association of Ideas; that connection between certain ideas which causes them to succeed each other involuntarily in the mind.

Assodes; a fever with excessive inward heat, though not so great externally. It is arranged by Cullen under the tertian remittents.

Assumption, in *Logic*, the postulate or thing supposed, which is the minor proposition in a syllogism.

Assumptive Arms. See Arms in *Heraldry*.

Assurance. See **Insurance.**

Astazof; an ointment of spemisla and houseleek.

Astchachilos; a gangrenous ulcer at the lower part of the feet.

Asterion, in *Astronomy*, the canis venaticus.

Asterism; a constellation of fixed stars.

Astern; behind a ship, as opposed to ahead; which implies the fore-part of the vessel.

Asteroides; the newly discovered planetary bodies. See **Astronomy.**

Asthma. This disease has not unaptly been called the plague spot of our climate, and as such it may be advisable to enter rather more fully into its symptoms and treatment than we usually do in our medical articles. It is of two kinds, the dry, and the humid or common asthma.

Asthma, observes Dr. Good, is more commonly a disease of the later than the earlier period of life; for it does not often appear in infancy or youth, although occasional instances of this have occurred, particularly in infancy, and have been mistaken for cases of croup, which the asthma of infancy very much resembles, though admitting of a more easy cure. It soon becomes habitual, and seems sometimes to be hereditary. It invades all temperaments, but more particularly the melancholic, or that which is a compound of the melancholic with the sanguineous.

The paroxysms of asthma are universally preceded by languor, flatulency, head-ache, heaviness over the eyes, sickness, disturbed rest, and a sense of fulness and anxiety about the præcordia. "When the evening approaches," says Dr. Bree, who unhappily described from his own history, "the weight over the eyes becomes more oppressive, and the patient is very sleepy. Frequently at this period there is a tingling and heat in the ears, neck, and breast. When an asthmatic person feels these warnings, he may be convinced that his enemy is at hand."

The accession is usually about the middle of the night, and during the first and deepest sleep: the cause of which may be thus explained. Respiration always takes place most easily in a raised or erect position, but in the night the body is recumbent. Respiration is also so much of a voluntary action, that although it continues during sleep, and when the will is not exerted, it is considerably aided by the concurrence of the will. Now, during sleep, this concurrence is wanting; and hence the most favourable period for the attack of this insidious complaint is that in which we actually find it makes its appearance—during a recumbent position of the body, when the muscles of respiration are destitute of the stimulus of volition. When the disease, indeed, has once established itself and become habitual, it will recur at other times also, but less frequently.

For the most part, the patient wakes suddenly, and feels a most distressing tightness about the chest, as if he were bound with cords: his anxiety is inexpressible, and he labours for breath as though every moment would be his last. He is obliged to sit erect, breathes distressfully with a wheezing sound, and cannot bear the weight of the bed-clothes. Cool fresh air is the object of his intense desire. At the same time the extremities are cold; the heart palpitates; the pulse is sometimes quickened, but usually weak, irregular, and often intermitting.

In treating asthma, attention must be directed to the paroxysm itself, and to the nature of the constitution after the paroxysm has ceased.

Dr. Cullen, who paid considerable attention to humid asthma, and who regarded plethora and turgescence of the blood-vessels as the usual cause, recommends blood-letting in the first attack, and especially in young persons; with the use of acids and neutral salts, as employed by Sir John Floyer, for the purpose of taking off the turgency of the blood. But the relief it affords, even in dry convulsive asthma, is very temporary; and Dr. Cullen allows that it cannot be persevered in without undermining the constitution and laying a foundation for dropsy. Dr. Bree regards it as a doubtful operation in the first species, or that, to adopt his own language, produced by ærial irritation, and as always imprudent in the second.

In this last, "I have repeatedly," says he, "directed it; but I have never had reason to think that the paroxysm was shortened an hour by the loss of blood: and I have often been convinced that the expectoration was delayed, and that more dyspnœa remained in the intermission than was common after former paroxysms. In old people, who have been long used to the disorder, it is certainly injurious. When, indeed, the disease is secondary, and depends evidently upon an overloaded liver or stomach, or some suppressed evacuation, active cathartics, and especially such as operate simply, will be of great use; and the increased action excited in the alvine canal will often take off the irregular action in the chest; but where the asthma is idiopathic, and especially where the constitution is infirm, as in old age, a powerful alvine irritation will exacerbate the spasm of the chest instead of diminishing it. In exciting nausea or vomiting, however, the patient may be less cautious; for each has often been found highly advantageous in both species of idiopathic asthma. The first, by diminishing generally the living power, and hereby relaxing the convulsive active, and at the same time determining to the surface. Riverius employed vomiting. Dr. Akenside was much attached to the practice of both; he vomited freely on the accession of the paroxysm, and often continued the same plan for a fortnight or three weeks, by giving from five to ten grains, or even a scruple of ipecacuana every other morning. Sir John Floyer extended the time beyond this, though he did not repeat the dose so frequently. He advises the operation of vomiting once in a month. Sedatives and antispasmodics have been found of considerable advantage.

Blistering may also be made use of, but, like setons or issues, can only be of ulterior advantage, for the fit must be of far more than ordinary length if it continue till the blister has produced vesication. It may, however, go far to prevent or shorten a relapse on the ensuing night; and especially when the disease is connected with an asthmatic habit.

There is no discharge that promises such direct benefit as that from the excretories of the bronchial vessels themselves; so is there no tribe of medicines on which we can place so much dependance as on expectorants, when judiciously selected and administered. In every kind of idiopathic affection these may be employed with advantage: for if there be a turgescence in the blood-vessels, they will have a tendency to emulge them; if the bronchiæ themselves be surcharged with serum or mucus, they will facilitate their exhaustion; or if their interior tunic be dry and irritable, by taking off the obstruction and restoring the deficient secretion, they will soften and lubricate the irritable membrane.

Of all the medicines, however, which act on the excernents of the lungs, the squill is by far the most to be depended upon. It is indeed a stimulant of the excernent system generally; for there is no part of this system capable of resisting its power: and it is hence necessary to watch its effects upon the kidneys and intestinal canal, and to attemper it with opium or some other guard, if it produce much influence in either of these ways; except, indeed, in the case of asthma connected with the phlegmatic habit, which is the only modification of the disease in which this collateral influence is found to be of advantage. Squills have also a peculiar tendency to stimulate the stomach, and produce nausea or vomiting; and it rarely shows much of an expectorating power till it has occasioned the former. But as these are advantageous to the disease in both species, and especially in humoural asthma, we are not to discontinue it on this account, but only to moderate its use.

As far as diet is concerned, it may be necessary to state, that the food should be light and cordial without being stimulant; of a solid rather than of a liquid kind; and the meal never be suffered to overload the stomach: all flautulent fruits and other vegetables should be avoided; but oranges, the alliaceous esculents, and the aromata may be allowed in moderation. Hot liquors should be sedulously abstained from; and the beverage consist chiefly of coffee, ginger-tea, and acidulated waters.

ASTRÆA. See VIRGO.

ASTRAGAL. See ARCHITECTURE.

ASTRAGAL, in *Gunnery*, the corner ring of a piece of ordnance.

ASTRAGALUS; the superior and first bone of the foot. See ANATOMY.

ASTRALISH; the ore of gold in its earliest state.

ASTRICTA; an epithet applied to the stomach in opposition to a state of relaxation.

ASTRICTION; the operation of astringent medicines.

ASTRICTORIA. See ASTRINGENTIA.

ASTRINGENTS; medicines of a binding character, such as the mineral acids and solutions of iron, zinc, and lead. The bark is also highly astringent.

ASTRINGENTIA; those things which have a binding quality, as Peruvian bark, &c.

ASTROBOLISMOS; another word for apoplexy.

ASTRODICTICUM; an instrument for several persons to view the stars at the same time, invented by Mr. Weighel.

ASTROGNOSIA; a knowledge of the fixed stars.

ASTROGNOSY, the science which teaches the constellations, ranks, &c., of the stars. (See ASTRONOMY.)

ASTROLABE, an instrument for measuring the degrees, minutes, and sometimes even the seconds, of angles. It generally consists of a horizontal circular plate of metal, having those divisions on its extreme circumference. The utmost accuracy may be obtained in the measurement of angles, by means of a peculiar contrivance (vernier), which consists of an arc, on which the smallest divisions of the circle are subdivided as minutely as is requisite in the observations, and as the skill of the maker can graduate it. This arc is moveable, so that it can be fitted to the divisions of the circle. Fixed to this circle are two indexes, provided with telescopes. One of them is immoveable; the other turns round the centre of the instrument. By taking sights from the vertex of the angle, at two fixed points in the direction of its sides, the arc, which measures the angle, is intersected on the circle of the instrument. In modern astronomy, this instrument is no longer used, except in the practical applications of geometry. The first application of the astrolabe to navigation was made by the physicians Roderic and Joseph, and Martin Behaim of Nuremberg, when John II., king of Portugal, desired them to invent a method of preserving a certain course at sea. They taught how to discover the situation of a vessel at sea without the use of the magnetic needle.

ASTROLOGY; an art which pretends to foretell future events, especially the fate of men, from the position of the stars. It is among the oldest superstitions in the world, and, as Bailly conjectures, with great apparent probability, it owes its origin to the influence of the heavenly bodies, particularly the sun and moon, on the seasons, the weather, and the fertility of the earth. This led to the idea that these luminaries were created only for the use of the planet we inhabit, and that, as they have an influence upon the earth, they probably have some connection with the destiny of individuals and of nations. The Egyptians have a tradition that Belus founded a colony from Egypt on the banks of the Euphrates, in Asia; and this colony was furnished with priests, according to the custom of the mother country, who were free from public taxes, and were called by the Babylonians *Chaldees*. Hence it may be conjectured, that astrology was invented by the Egyptians; among whom the inhabitants of Thebes particularly claimed the honour of the invention. Most of the ancient writers are agreed, that astrology was communicated by the Chaldees to other nations. From this circumstance, astrologers used to be called *Chaldees* by the ancient writers; sometimes *Genethliaci* (see GENETHLIACON); and, in later times, *Chaldee* has been synonymous with *astrologer*. (See HOROSCOPE.) The great antiquity of this art may be inferred from the fact, that most astrological observations are founded on the position of the stars in reference to the horizon, which was the first circle recognized in the heavens; also from its being mentioned in the Mosaic history. As astrology in later times fell into disrepute on account of the cupidity and fraud of its practitioners, these assumed the name of *Mathematicians*, by which they were generally known at the time of the Roman emperors. They caused so much trouble, that Tiberius at length banished them from Rome. The law relating to this banishment of astrologers, however, makes a distinction between geometry and what they term the mathematical or astrological art. However objectionable astrology may be in itself, it has been of essential use to astronomy. It has excited more interest in, and led to more careful observations of, the heavenly bodies. During the middle ages, astrology and astronomy were cultivated in connection by the Arabs, and their works on the subject are still extant. Pico of Mirandola, who manfully combatted the errors of astrology towards the close of the fifteenth century, found but little attention paid to his labours. Even in the sixteenth and seventeenth centuries, astrology could boast of literary men, such as Cardano, and even Kepler, among its adherents. The Copernican system, the correctness of which experience has been continually confirming, has shaken the foundations of the ancient science; but the disease is not wholly eradicated.

ASTROMETEOROLOGIA; the art of foretelling weather. See BAROMETER.

ASTRONOMICAL; an epithet for any thing relating to astronomy, as *Astronomical day*, hour, or year, in distinction from the civil day, hour, or year.—*Astronomical characters*, those used in astronomy.—*Astronomical horizon*, in distinction from the sensible horizon.—*Astronomical place of a star* or planet; the longitude of a star or place in the ecliptic, reckoned from the beginning of Aries.—*Astronomical hours;* such as are reckoned from the noon or mid-day to the noon or midnight of another.—*Astronomical observations;* such observations as are made with suitable instruments by astronomers on the heavenly bodies to ascertain their forms, appearances, motions, &c. The observations of Hipparchus, which are the earliest handed down to us from the Greeks, are given in Ptolemy's *Amalgest.*—*Astronomical tables* are computations of the motions, places, and other phenomena of the planets, both primary and secondary. Tables of this description are to be found in Ptolemy's *Amalgest,* which have however been superseded by more modern and correct calculations, the principal of which is the nautical almanack.

ASTRONOMICAL CALENDAR; an instrument consisting of a board on which is pasted an engraved paper, with a brass slider, which carries a fine line, and shows at sight the meridian altitude and declination of the sun.

ASTRONOMICAL QUADRANT; a mathematical instrument for taking observations of the sun.

ASTRONOMICAL TELESCOPE; so called, because it is only used in astronomical observation, consists of an object-glass, and an eye-glass, both convex.

ASTRONOMICAL SECTOR; an instrument for finding the difference in right ascension and declination between two objects whose distance is too great to be seen through a fixed telescope.

ASTRONOMY is the science of the heavenly bodies, and describes their motions, periods, eclipses, magnitudes, &c. The popular modes of illustrating this science, both in the lecture-room and in general treatises, are but of little value to the astronomer; and we purpose in the present article combining the practice of the science with a description of the heavenly bodies, so that our readers may acquire not only a popular view of astronomy, but learn how to determine for themselves the data on which the great truths of this interesting science are founded.

The study of the heavens was undoubtedly coeval with the existence of man, urged by the double impulse of his necessities and fears. In the genial climate, and beneath the serene sky of the East, it seems to have made considerable progress. The great convulsion in the physical world, of which the sacred writings have traced the outline, swept away along with the races of men all the records of their intellectual attainments; but some wrecks of their astronomical knowledge seem to have been preserved either by the durability of the monuments on which they had been engraved, or by the memories of those whom the desolating waters had spared. These precious relics, which time still respeets, inspired the Chaldean, Indian, and Egyptian philosophers with a reverence for astronomy, and formed the epochs of the science which they restored. From Egypt it speedily passed into Greece under the form of mysteries too sacred for the ear of the vulgar, and of allegorical emblems too profound for their understanding. Here it was soon stripped of the mystical drapery in which superstition had swathed it, and the genius of that refined people presented it purified and improved in all their schools of philosophy. In the tenets of Thales, Pythagoras, and their successors, we trace some of the soundest doctrines of modern astronomy, which form a singular contrast with the reveries of solid orbits and the harmony of the celestial spheres.

Astronomy was now destined to receive into the land of its birth all the advantages of royal patronage, and that science, which Rome despised, and which Athens persecuted, found shelter among the sovereigns of Alexandria. The establishment of the Alexandrian school, and the protection and cultivation of the sciences by men who had lived in war, is the most glowing passage in the history of the human mind. It is the romance, indeed, of astronomy which princes should peruse, and which statesmen should engrave upon their heart. The formation of the library of Alexandria; the erection of its observatory; the invitation to his court of the philosophers of every clime; his participation in their conversation and in their labours, and the accessions which astronomy thence derived, have immortalized the name of Ptolemy Philadelphus, while they reflected over the darkness of future times a more intense light than was ever thrown by her blazing Pharaohs upon the shelves of her rugged shores.

Aristarchus, one of the earliest astronomers of this great school, determined that the distance of the sun was at least twenty times greater than that of the moon; and, convinced that the earth moved round the sun, he inferred from the positions of the stars, when the earth was in the opposite points of its orbit, that their distances were immeasurably greater than that of the sun. These important steps in the science were pursued by Eratosthenes, whom Ptolemy Euergetes invited to his capital. With instruments erected by his patron, he found that the diameter of the sun was at least twenty-seven times greater than that of the earth; and by comparing the distance of Alexandria and Syene with the celestial arc between the zeniths of these two cities, he concluded that the circumference of the earth was twenty-five thousand stadia; a result not excessively different from the measurement of modern times. Important as these determinations were to astronomy, yet it was from his successor, Hipparchus, that the science derived the most valuable improvements. Collecting and comparing the observations of his predecessors, he resolved to repeat and to extend them. He ascertained the length of the tropical year; he discovered the equation of time; he fixed the lunar motions with great accuracy, and he determined the eccentricity and the inclination of the moon's orbit. His grand work, however is his *Catalogue of the Longitudes and Latitudes of One Thousand and Twenty-two Fixed Stars;* by means of which he discovered the precession of the equinoctial points. In carrying on these inquiries, he was led to the principles and rules of spherical trigonometry, one of the most valuable branches of geometry. The leading works of this eminent astronomer perished in the flames which destroyed the Alexandrian library, but the most important of his observations have been fortunately preserved in the writings of his successors.

The great advances which were thus made in the science were succeeded by a long interval of dark-

ness, across which a few gleams of light were occasionally thrown. The Alexandrian school, however, still existed; and the consecrated name of Ptolemy, so indelibly associated with its origin, was destined in its latter days to renew its glory. About one hundred and thirty years before the Christian era, Ptolemy devoted himself to the science of the heavens. He discovered the second inequality in the moon's motions; he determined with new accuracy the relative positions of the planets, and their distances from the earth; but rejecting, on the evidence of his senses, the system of Pythagoras, who made the earth the centre of the universe, round which the sun and the whole starry heavens performed their revolutions. This fundamental error led him to explain the stations and retrogrations of the planets, and the other celestial motions, by the cumbrous machinery of epicycles, which so long deformed the science and retarded its advancement. The subject of astronomical refractions received also from Ptolemy a satisfactory explanation; but though he rendered such signal services to astronomy, as well as to the science of optics, dialling, and music, yet his name will for ever be connected with a false system of the universe; and his assiduity as an observer will always be placed in disagreeable contrast with that defect of sagacity which had thus marked his astronomical speculations.

With the life of Ptolemy terminated the labours of the Alexandrian school. Centuries rolled on amid intellectual darkness: ambition pursued her bloody course, and superstition continued to offer her unholy sacrifice; but no gifted spirit arose to vindicate the science of the heavens from its degraded state. Even the accumulated knowledge of former times perished in the conflagration of the Alexandrian library; and though the tears of the victorious caliph flowed in repentance, yet they were a poor compensation for the havoc of his arms.

But while the Arabs had thus wantonly violated the sanctuary of science, their own land was ordained to be the scene of its triumphs. Astronomy was again received into the palaces of kings, and Almansor, Al Raschid, and Almamon, were its cultivators as well as its ardent patrons. The rays of science gilded the minarets of Bagdad when they had ceased to shine on benighted Europe. The Amalgest of Ptolemy was recovered from the Greek emperor by force of arms; and several works were composed and observations made, which powerfully contributed to the science of astronomy. Even in Persia and Tartary, associations of astronomers were formed by the command of their princes; magnificent instruments were erected at the royal expense; and catalogues of the fixed stars, and astronomical tables of singular accuracy proceeded from the pen of the grandson of Tamerlane the Great. From the East, astronomy passed with the arms of the Arabs into Spain, where it received valuable additions from the genius of Alhazen and Alphonso X. The Alphonsine Tables, indeed, which appeared in 1252, are to this day a monument of the knowledge and liberality of the Castilian king. We now approach the era of reviving science. Many astronomers of inferior note paved the way, by valuable, though insulated observations, for the great restorer of astronomy. Copernicus, who was born in 1437, was not the author of any remarkable discovery; but by a diligent comparison of the discoveries of his predecessors, by sagacious views of the simplicity of nature, and by a just perception of the relations which ought to exist among the various bodies of the system, he was led to place the sun in the centre of the universe, and to account for the daily revolution of the celestial sphere by the motion of the earth upon its axis. This slight change upon the Ptolemaic system banished the epicycles and eccentrics of his predecessors, and every phenomenon in the general motions of the heavens received an immediate explanation. The publication, therefore, of the *Astronomia Instaurata* in 1530, forms a principal epoch in the history of astronomy. The true solar system was now established, and the various planets which the unassisted eye could discover in the heavens, were placed in their proper spheres, and nearly at their proper distances from the central luminary; while the fixed stars, separated from our planetary universe, were thrown back into the depths of space, to become in their turn the objects of a more refined philosophy.

Hitherto astronomy was merely a science of observation, and no stretch of mind was required to comprehend its principles or its details. It was now destined to take a higher and a wider flight, and to call into its service the most profound and varied acquirements. The subject of the refraction of the atmosphere had formed a slight connection between astronomy and optics; but the invention of the telescope now bound these sciences together by an indissoluble tie, and from the latter the former derived all its subsequent discoveries. In a few years the ring of Saturn and nine secondary planets rewarded the labours of Galileo, Huygens, and Cassini; and the application of the pendulum to clocks by Huygens furnished the astronomer with one of his most valuable instruments. The period, however, of which we now treat has derived its distinctive feature from the determinations of the laws of the planetary motions by Kepler and Newton. Fond of analogies, Kepler directed his mind to the discovery of general laws: he found that all the planets revolved in elliptical orbits, in one of the foci of which the sun was placed. He discovered that the line which joined the sun and the planet described equal areas in equal times; and by comparing the powers of the numbers which represent the periods and the distances of the planets, he determined that the squares of their periods round the sun, varied as the cubes of the greater axes of their elliptical orbits. These great discoveries paved the way for views still more comprehensive. Kepler had been indulged with a faint glimpse of the mutual tendency of all bodies to one another; and Dr. Hook went so far as to show that the motions of the planets were produced by the attractive agency of the sun, combined with the force which had originally projected them: but it was reserved for Newton to establish the law of universal gravitation in its entire generality, and to apply it with demonstrative evidence to all the movements within the solar system. In assimilating the power by which the apple falls from the tree, to that which retains the moon in her orbit, Newton made the first step in this great generalization. He soon perceived that all the other satellites revolved round their primary planets in virtue of their attraction, and that the primary, along with the secondary planets, were carried round the sun by the agency of his predominating attraction. Hence, he was led to deduce the general principle, that all material bodies attract each other with a

force directly proportional to the number of their particles, and inversely proportional to the squares of their distances. The tides, the spheroidical form of the earth, the precession of the equinoxes, and the irregularities of the lunar motions, received from this comprehensive proposition, an immediate explanation; and the laws of the material universe, rescued from the schools of a false philosophy, were now fixed upon an imperishable base.

If England may be permitted to cast a proud eye upon the period we have been considering, she cannot but contemplate with the bitterest dejection that which succeeded it. As if Providence decreed that there should be a balance in the glory, as well as in the power of nations, no British name has been allowed to share in the intellectual triumphs which illustrated the middle and the close of the eighteenth century. Truth and justice demand from us this afflicting acknowledgment, while they award to Clairaut, Euler, D'Alembert, Lagrange, and Laplace, the highest honour of having completed the theory of the system of the world.

The problem of two bodies, or the determination of the motions of one planet revolving round another, had received from Newton the most perfect solution. He had even shown that the problem of three bodies, in which the action of a disturbing planet is introduced, could be resolved by the principles which he had established; and in the case of the lunar irregularities, he had succeeded in explaining no fewer than five of the most important. At this point, however, the powers of analysis failed, and it was left to a succeeding age to complete the noble edifice which he had founded. The results of the labours to which we allude, are developed in the *Mécanique Céleste* of Laplace, a work which ranks next to the *Principia*; but it would exceed our limits were we to assign to each of the astronomers we have named their respective claims to immortality. By the improvements they have made in the analytical art, they have solved the problem of three bodies, and have computed, with an accuracy almost miraculous, the various disturbances which affect the motions of the principal planets.

But though the spirit of English science had thus been slumbering amid the intrigues of faction, and the apathy of short-lived and unenlightened administrations, the exertions of individual genius were preparing in secret for new achievements. The invention of the achromatic telescope by Dollond, and the improvement of reflectors by Short and Mudge, had armed the observer for the great subject of sidereal astronomy; for examining the phenomena and condition of the stars, and the structure of the groups and systems which the telescope descried in the immensity of space. In this period, doubtless the most brilliant in the annals of discovery, the name of Herschel stands in proud pre-eminence as the founder and the most successful cultivator of sidereal astronomy; and when we add the name of his accomplished son, of Dr. Brinckley (Bishop of Cloyne), of Sir James South, and of Mr. Struve, we complete the list of great men who have immortalized themselves in this difficult and boundless field of inquiry. Before we proceed to give an account of their labours, it is necessary that the reader should have some idea of the distance and magnitudes of the bodies which are to come under his consideration. That the nearest of the fixed stars are not placed at immeasurable distances, has been fully established by the numerous and ably conducted observations of the Bishop of Cloyne.

It was to regions so remote, and to bodies so vast, that Sir William Herschel directed his powerful telescopes, after he had extended the limits of our own system, by the discovery of one primary and eight secondary planets. Professor Kant and the celebrated Lambert had suggested the hypothesis, that all the bodies in the universe were collected into nebulæ, and that all the insulated and scattered stars formed part of the nebulæ to which our own system belonged. Pursuing this happy thought, Sir William Herschel examined no fewer than 2,500 nebulæ, and he was led to the opinion that the galaxy, or milky-way, was the projection of our own nebulæ in the sky; and by gauging the heavens, or counting the number of stars which occur in the same space in different directions, he was enabled to determine the probable form of the nebulæ itself, and the probable position of the solar system within it. But while this idea impresses us with its grandeur, it at the same time furnishes us with a scale for estimating the immensity of nature. If all the separate stars which the most powerful telescope can descry, are only part of our own nebulæ, what must we think of the millions of nebulæ, some of which exhibit by their proximity the individual stars of which they are composed? while others, as they recede from our failing sight, display only in the best instruments a continuous and unbroken light, in which the spaces between the stars can no longer be seen. From the systems which roll within these groups of worlds, a new firmament of stars will be seen, and each system will have its milky-way, exhibiting the projection of its nebulæ, varying in form and in lustre with its locality within the group. It is in vain to pursue ideas so vast and overwhelming: it is enough that the mind tries its strength, and stands self-convicted of its weakness.

Let us, therefore, turn our attention to nearer objects—to our own nebulæ, and the stars which compose it. Not content with determining the probable position of the solar system within the nebulæ of the milky-way, Sir William Herschel conceived the idea of ascertaining whether that system was stationary or moveable. By a comparison of the proper motions of the fixed stars, he determined that the solar system was advancing towards the constellation Hercules; and that if it were viewed from one of the nearest of the fixed stars, the sun would appear to describe an arch of about one second. In reasoning respecting the insulated stars, which belong to what we may now call the solar nebulæ, he justly conceived that those which were double must form binary systems, or systems in which the two stars revolve round their common centre of gravity. These views, at first entirely speculative, received from subsequent and long-continued observation a very remarkable confirmation. If we suppose a line to join the centres of the two stars which compose a double star, then if the two stars have no relative motion, this line must form an invariable angle with the line or direction of their daily motion. By means of an ingenious position-micrometer, Sir William Herschel determined this angle (called the angle of position) for seven hundred and two stars, between 1778 and 1784. After a lapse of twenty years, he repeated his observations on the same stars, between 1800 and 1805, and

he had the satisfaction of finding that in more than fifty double stars there had been a decided change, either in their distance or in their angle of position. In this way he discovered that one of the stars of Castor revolved round the other in 342 years; that the small star of γ, Leonis, performed its circuit in 1200 years; that of ϵ, Boötes, in 1681 years; that of δ, Serpentis, in 375, and that of γ, Virginis, in 708 years. By this great discovery, the greatest unquestionably in the history of astronomy, the existence of systems among the fixed stars was completely established; but so far did Sir William Herschel's labours transcend those of the age in which he lived, that no attempt was made to repeat and to extend them. They were scarcely admitted into any astronomical work; they were ridiculed by men whose reputation had been eclipsed by his own; and they were received with a sort of incredulous wonder, even by the most ardent lovers of astronomy. The progress of knowledge and of discovery had paved the way not only for the highest achievements of Newton and Laplace, but also for their immediate reception among philosophers; and had these great men never lived, science would in a few years have received from other minds the same splendid accessions. The discoveries of Herschel, on the contrary, exhibited no continuity with those of his predecessors. Before his day sidereal astronomy had no existence; nor had the wildness of speculation ventured even to foreshadow its wonders. Entrenched in the remoteness of space, and among spheres which no telescope but his could descry, her walls were unscaled, and her outworks even unapproached. His genius, however, enabled him to surmount barriers hitherto impregnable, and conducted him in triumph into the very stronghold of her mysteries. The cessation of such gigantic labour would have been afflicting to science, had not that same wisdom which provided for the continuity of his name, provided also for the continuity of his labours.

In the year 1816, four years before the death of his venerable father, Mr. (now Sir John) Herschel, had begun a re-examination of the double stars, and had made some progress in it. The same idea had occurred to Sir William South, one of the most able and enterprising astronomers of the present day, and it was agreed that they should undertake the work in concert. They accordingly began in March 1821, and continuing their observations in 1822 and 1823, they were able to communicate to the Royal Society in January 1824, the position and apparent distances of 380 double and triple stars, the result of above 10,000 individual measurements. The instruments which they employed were two achromatic telescopes mounted equatorially: the object-glass of the smallest had an aperture of three inches and three quarters, and a focal length of five feet, and was made by the late P. and J. Dollond. The power usually employed was 133, but powers of 68, 116, 240, and 381, were sometimes used. The largest telescope was seven feet in focal length, with an aperture of five inches, and is supposed to be the best that Mr. Tulley ever executed. The power commonly employed was 179, though 105, 273, and sometimes 600 were used.

No sooner had Sir William South completed his share in this great work, than he began another series of observations of equal difficulty and importance. They were made principally at Passy, near Paris, with the instruments above mentioned; and in November, 1825, he communicated to the Royal Society the apparent distances and positions of 458 double stars, of which 160 had never before beer observed.

While these observations were going on in England, an able continental astronomer, M. Struve, director of the Imperial Observatory at Dorpat, in Livonia, had occupied himself with the same subject; and such was his assiduity and zeal, that in four years he completed his *Catalogus Novus Stellarum Duplicium et Multiplicium*, containing no fewer than 3063 stars. These observations were chiefly made with a telescope by Frauenhofer, which the Emperor of Russia had presented to the observatory of Dorpat. This magnificent instrument has a focal length of thirteen feet, and an aperture of nine inches, and cost thirteen hundred pounds. The King of Bavaria followed this noble example, by ordering a still finer instrument for the same purpose.

The early history of astronomy was, as we have seen, fraught with error; but observation has now enabled us to trace with mathematical accuracy the forms and motions of the heavenly bodies. The planets known as forming part of our system are eleven in number, and we cannot do better than enumerate them in the order in which they follow from the sun; omitting however our earth, which will be the subject of a more minute examination, with especial reference to the phenomena of the seasons, day and night, &c. It may be right to observe, that all the planets move round the sun from east to west, and the paths in which they move are called their orbits.

The one whose orbit is nearest to the sun, is called *Mercury*. When seen through a telescope, it sometimes appears in the form of a half moon, while at other times a little more or less than half its disc is seen; hence it is inferred, that it has the same phases as the moon, except that it never appears quite round, as its enlightened side is only turned directly towards the earth when it is so near the sun as to become invisible on account of the splendour of the sun's rays. The enlightened side of this planet being always directed towards the sun, and it never appearing round, are evident proofs that it shines by reflected light. The best observations of this planet are those made when it is seen on the sun's disc, called its transit; for in its lower conjunction, it sometimes passes before the sun, like a small spot, eclipsing a part of the sun's body.

Mercury performs its periodical revolution round the sun in 87 days, 23 hours, 15 minutes, 43 seconds; its greatest elongation is 28° 20′, distance from the sun 36814721 miles; the eccentricity of its orbit is estimated at one-fifth of its mean distance from the sun; its apparent diameter 11′; hence its real diameter is 3108 miles; and its magnitude about one-sixteenth of the magnitude of the earth.

Mercury emits a bright white light; it appears a little after sun-set, and again a little before sun-rise; but on account of its nearness to the sun, and the smallness of its magnitude, it is seldom seen. The light and heat which this planet receives from the sun, are about seven times greater than the light and heat which the earth receives. The orbit of Mercury makes an angle of seven degrees with the ecliptic, and it revolves round the sun at the rate of upwards of one hundred and nine thousand miles per hour.

Venus is the second planet. When viewed through a good telescope, it has a very pleasing appearance. At the time of its greatest elongation, it appears like the moon in the quadratures; one half of its disc being enlightened. In the inferior part of its orbit, as its elongation decreases, the enlightened part becomes less. After passing the inferior conjunction, the planet is again seen crescent-shaped, but the illuminated part continues to decrease, and at the greatest elongation half its disc is again seen enlightened. In the superior part of its orbit, as its elongation decreases, its face becomes more full and round, till the superior conjunction, after which time it is again diminished by the same gradation as its increase was in the former case accomplished. There is no difficulty in accounting for this variety of phases, it being occasioned by the different positions of Venus with respect to the Sun and Earth; for as the enlightened face of Venus must of course be always opposite to or facing the sun, it will be more or less visible to us according to our situation at various times.

The surface of Venus is diversified with spots like our moon, by the motion of which it is determined, that it revolves on its axis from east to west in the space of about twenty-three hours. Under favourable circumstances, mountains like those in the moon may, it is said, be discerned with a very powerful telescope.

A body which weighs one pound at the equator of the earth, would, if removed to the equator of Venus, weigh only 0.98 pound.

The proportion of light and heat which she receives from the sun is about 1.91 times greater than that received on the earth.

As viewed from the earth, Venus is the most brilliant of all the planets; and may sometimes be seen with the naked eye at noon day. She is generally known as the morning and evening star, and never recedes far from the sun. The mean distance of Venus from the sun is 0.7233316; that of the earth being considered as unity. This makes her mean distance nearly 68 millions of miles.

Passing our earth, which will be fully noticed hereafter, we come to the planet *Mars*, which is peculiarly distinguished by its dusky red colour. By the spots on *Mars*, its diurnal revolution is ascertained in the direction from west to east. From the ruddy and obscure appearance of this planet, as well as from other appearances, it is concluded that its atmosphere is nearly of the same density as that of the earth. Herschel has observed, that two circles surrounding the poles of this planet are very white and luminous, probably from snow lying there. The mean distance of Mars from the sun is 1.5236923; that of the earth being considered as unity. This makes this mean distance above 142 millions of miles. He performs his mean sidereal revolution in 686.9796458 mean solar days; or in 686 days, 23 hours, 30 minutes, 41 seconds, 4: and his mean synodical revolution in 779.936 mean solar days.

A body which weighs one pound at the equator of the earth, would, if removed to the equator of Mars, weigh only one-third of a pound.

The proportion of light and heat received by him from the sun is about 0.43; that received by the earth being considered as unity.

He is not accompanied by any satellite, and is known by his red and fiery appearance.

His course sometimes appears retrograde. The arc which he describes in such cases varies from 10° 6′ to 19° 35′: its duration in the former case is 60 days, 18 hours; and in the latter case 80 days, 15 hours. This retrogradation commences or finishes when the planet is at a distance from the sun, which varies from 128° 44′ to 146° 37′.

The next planet in our system is *Vesta*, for the knowledge of which we are indebted to Dr. Olbers of Bremen, being first discovered by him, March 29, 1807. Its distance from the sun is about 223 millions of miles, and its annual revolution in its orbit is performed in 3 years, 7½ months. But neither has its diameter, nor the duration of diurnal rotation, been yet ascertained.

Juno, the next in order, is another new planet; discovered by Mr. Harding, at the observatory at Lilienthal, near Bremen, September 1, 1804. The mean distance of this planet from the sun is estimated at 253 millions of miles, and its annual revolution is performed in 4 years, 4 months, and 6 days; but its diameter, and the time of its revolving on its axis, are unknown.

Ceres was first discovered by Piazzi of Palermo, January 1, 1801. Its mean distance is nearly the same as that of Pallas, and consequently its annual revolution is performed in nearly the same time.

The next superior planet is *Pallas*, which was first observed by Dr. Olbers, March 8, 1812: the mean distance of which from the sun is reckoned to be about 263 millions of miles, and its revolution in its orbit is made in about 4 years, 7 months, and 10 days; but, like the two former, its diameter and diurnal rotation have not as yet been correctly ascertained.

Jupiter is, next to Venus, the most brilliant of the planets, and sometimes even surpasses it in brightness. Its apparent diameter at its mean distance from the earth is 36″. Its figure is an oblate spheroid, the proportion of its equatorial to its polar axis being about 14 to 13. Laplace from theory deduces this proportion to be 1,000,000 to 9,286,922, the result obtained from computing the effect of the equatorial regions of the planet in disturbing the nodes of the satellites. When seen through a telescope, this planet exhibits a very remarkable appearance, its surface being covered with a number of belts or stripes of various shades. These appearances differ much at different times, and even at the same time in telescopes of different powers. These belts were first observed at Naples by Zuppi and Bartoli, two Jesuits; and about the year 1660, they were observed by Campini, with refracting telescopes of his own construction, and not much inferior in distinctness to those of the present day; the great modern improvement in refracting telescopes consisting rather in the reduction of their size than in the increase of their magnifying power.

Jupiter is accompanied by four satellites, which were discovered by Galileo, the 8th of January 1610. He at first took them for telescopic fixed stars; but continued observation soon convinced him that they really accompanied the planet. The relative situation of these small bodies changes at every instant: they oscillate on each side of the planet, and it is by the extent of these oscillations that the rank of these satellites is determined; that being called the first satellite, whose oscillation is the least. They are sometimes seen to pass over the disc of the planet,

and project a shadow in the form of a well-defined black spot, which then describes a chord of this disc.

Jupiter and his satellites, therefore, are opaque bodies, enlightened by the sun; and when the latter interpose between the sun and Jupiter, they produce real solar eclipses, precisely similar to those which the moon occasions on the earth.

These phenomena lead to the explanation of another which the satellites present. They are often observed to disappear, though at some distance from the disc of the planet: the third and fourth reappear sometimes on the same side of the disc.

The shadow which Jupiter projects behind it (relatively to the sun) is the only cause that can explain these disappearances, which are perfectly similar to eclipses of the moon. The circumstances which accompany them leave no doubt of the reality of this cause. The satellites are always observed to disappear on the side of the disc opposite to the sun, and consequently on the same side to which the conical shadow is projected. They are eclipsed nearest the disc, when the planet is nearest to its opposition.

Finally, the duration of these eclipses answers to the time which should elapse while they transverse the shadow of Jupiter.

Thus it appears that these satellites move from west to east in returning orbits round the planet. Observations of their eclipses are the most exact means of determining their motions. Their mean sidereal and synodical revolutions, as seen from the centre of Jupiter, are very accurately determined by comparing eclipses at long intervals from each other, and observed near the opposition of the planet.

Saturn can hardly be seen by the naked eye. When examined by a telescope, it exhibits a very remarkable appearance. It is surrounded by a thin, flat, broad, luminous ring, which encompasses the body of the planet, but does not touch it. This ring casts a strong shadow upon the planet, and is divided into two, by a distinct line in the middle of its breadth. The rings are circular, but appear elliptical from being viewed obliquely.

According to Dr. Herschel, the dimensions of the rings, and the space between, are as follow:

	Miles.
Inner diameter of the smaller ring . . .	146,345
Outside diameter of ditto	184,393
Inner diameter of the larger ring	190,248
Outside diameter of ditto	204,883
Breadth of the inner ring	20,000
Ditto of the outer ring	7,200
Ditto of vacant space	2,839

Besides this ring, Saturn has seven moons of different sizes, and its body is surrounded also by belts, like those of Jupiter.

The mean distance of this planet from the sun is 9.5387861; that of the earth being considered as unity. This makes its mean distance about 890 millions of miles. His mean sidereal revolution is performed in 29.456 Julian years. The rotation on his axis is performed in about ten hours and a half. His true diameter is about 76068 miles.

Uranus, or the *Georgium Sidus*, is the last planet known in our system. It was discovered by Sir William Herschel, March 13th, 1781, who gave it the name which it now bears. It performs its sidereal revolution in about 30,686 mean solar days, or in about 84 Julian years.

Its distance from the sun is upwards of nineteen hundred millions of miles; and its apparent diameter is scarcely 4",0.

Six satellites accompany this planet, which move in orbits nearly perpendicular to the plane of the ecliptic.

The sizes and relative situations of the *sun*, *earth*, and *moon*, will now engage our attention. It will hardly be necessary to state that the first of these great bodies forms the centre of our system, round which the planets and satellites revolve, or rather round the common centre of gravity of the entire series.

The first thing that strikes the mind when contemplating this glorious orb, is its astonishing magnitude. This vast globe is found to be about 882,000 miles in diameter, and, consequently, contains a mass of matter equal to more than thirteen hundred thousand spheres the size of our earth.

The only motion which an ordinary observer can trace in the sun is one of rotation, on its axis in the space of rather more than twenty-five days. This motion has been ascertained by means of a variety of dark spots, which are discovered by the telescope on the sun's disc. They first appear on his eastern limb, and after a period of about thirteen days, disappear on his western. These spots vary both in number, magnitude, and shape; sometimes 40 or 50, and at other times only one or two are visible. Most of them have a very dark nucleus, or central part, surrounded by an umbra, or faint shadow. Some of the spots are as large as would cover the whole continent of Europe; and one was seen in the year 1779, which was computed to be more than fifty thousand miles in diameter. With regard to the nature of this globe, it appears highly probable, from the observations of Sir William Herschel, that the sun is a solid and opaque body, surrounded with luminous clouds which float in the solar atmosphere, and that the dark nucleus of the spots is the opaque body of the sun appearing through occasional openings in its atmosphere.

The following are Sir Isaac Newton's observations on the sun; 1. That its heat is seven times greater in Mercury than with us, and that water there would immediately disappear in the state of vapour. 2. That the quantity of matter in the sun is to that of Jupiter as 1100 to 1; and that the distance of Jupiter from the sun is in the same ratio to the sun's diameter; consequently the centre of the sun and Jupiter is nearly in the superfices of the former. 3. That the quantity of matter in the sun is to that of Saturn as 2360 to 1; and the distance of Saturn from the sun is in a ratio little less than that of the sun's semi-diameter, so that the common centre of gravity of Saturn and the sun is a little within the latter. 4. Hence the common centre of gravity of all the planets cannot be more than the length of the solar diameter from the centre of the sun.

From other observations, which we cannot detail without far exceeding our prescribed limits, Sir W. Herschel was induced to suppose, that the appearance of copious spots indicated the approach of warm seasons on the surface of the earth; and he endeavoured to maintain this opinion by historical evidence; connecting the varying temperature of our atmosphere with the appearance and disappearance

of the solar spots. The spots or shallows, which our author considers as parts of an inferior stratum, consisting of opaque clouds, are capable of protecting the immediate surface of the sun from the excessive heat produced by combustion in the superior stratum, and perhaps of rendering it habitable to animated beings. But if stars are suns, and suns are habitable, a very extensive field of examination is thus opened to our view.

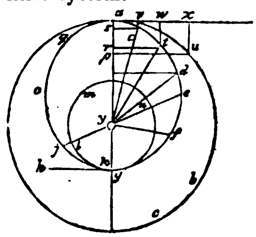
Some distinguished philosophers, among whom we may reckon Sir Isaac Newton, consider the sun's rays as composed of small particles, which move with uniform velocities in uniform mediums, but with variable velocities in mediums of variable densities. These particles, they say, act upon the minute constituent parts of bodies, not by impact, but at some indefinitely small distance; they attract and are attracted; and on being reflected or refracted, they excite a vibratory motion in the component particles. Others, represent fire as a substance sui generis, unalterable in its nature, and incapable of being produced or destroyed; natually existing in equal quantities in all places, imperceptible to our senses, and only discoverable by its effects, when it is collected in a less space than that which, from its tendency to an universal and equable diffusion, it would otherwise occupy. It has also been argued, that the matter of the sun's rays is not derived from the sun in any shape, but that the rays, whether direct or reflected, are of use only as they impel the particles of fire in parallel directions: that parallelism being destroyed, by intercepting the solar rays, the fire instantly assumes its natural state of uniform diffusion.

M. de Luc, in his *Lettres Physiques*, is of opinion, that the solar rays are the principal cause of heat; but that they only heat such bodies as do not allow them a free passage. In this respect he agrees with Newton; but then he differs totally from him concerning the nature of the rays of the sun. He does not admit the emanations of any luminous corpuscles from the sun, or rather self-shining substances, but supposes all space to be filled with an ether of great elasticity and small density, and that light consists in the vibrations of this ether, as sound consists in the vibrations of the air. Upon Newton's supposition, says an excellent writer, the causes by which particles of light, and the corpuscles constituting other bodies, are mutually attracted and repelled, is uncertain. The cause of the uniform diffusion of fire, by a series of vibrations, as already stated, is equally inexplicable; and we add to the other difficulties attending the supposition of an universal ether, by the want of a first mover to make the sun vibrate. See Light.

We do not in the present case propose, mathematically, investigating the doctrine of gravitation, or the motions of the heavenly bodies, but it will be necessary to premise, that there are two forces in continued operation, the one termed the *centripetal*, the other the *centrifugal*, the first tending to draw all bodies towards each other, while the second acts in precisely the opposite direction. This species of universal attraction, which was first examined by our own immortal Newton, and to which his attention was accidentally drawn by the fall of an apple from a tree, is but a branch of the same system of forces which holds all the bodies on the earth's surface together. Iron owes its tenacity to the attraction of cohesion, and it is a similar force which causes the drops of falling rain to be spherical. This fact has been beautifully illustrated by a modern poet—

> "That self-same law which moulds a tear,
> And bids it trickle from its source;
> That law preserves the earth a sphere,
> And guides the planets in their course."

The mutual attraction between the planets and the sun keeps them from flying off from their orbits by the centrifugal force, which is generated by their revolving in a curve; and the latter force again keeps them from falling into the sun, which would be the case, if it were not for the motion impressed upon them. Thus these two powers balance each other, and preserve order in the entire system.



This doctrine, which is founded on the demonstrations of Sir Isaac Newton, may be thus illustrated. If a planet, as our earth at *a*, gravitates, or is attracted towards the sun, *y*, so as to fall from *a* to *p*, in the time that the projectile force would have carried it from *a* to *x*, it will describe the curve *a u* by the combined action of these two forces, in the same time that the projectile force, singly, would have carried it from *a* to *x*, or the gravitating power, singly, have caused it to descend from *a* to *p*; and these two forces being duly proportioned, the planet obeying them both, will move in the circle *a u b c*. But, if whilst the projectile force would carry the planet from *a* to *v*, the sun's attraction should bring it down from *a* to *f*, the gravitating power would then be too strong for the projectile force, and would cause the planet to describe the curve *a c*. When the planet comes to *c*, the gravitating power (which always increases as the square of the distance from the sun, *y*, diminishes) will be yet stronger, for the projectile force, and by conspiring, in some degree, therewith, will accelerate the planet's motion all the way from *c* to *g*, causing it to describe the arcs *a a d e f*, &c., all in equal times. Having its motion thus accelerated, it thereby acquires so much centrifugal force, or tendency to fly off at *g*, in the line *g h*, as overcomes the sun's attraction; and the centrifugal force being too great to allow the planet to be brought nearer to the sun, or even to move round him in the circle *k l m*, &c. it goes off, and ascends in the curve *g j o q*, &c., its motion decreasing as gradually from *g* to *a* as it increased from *a* to *g*, because the sun's attraction now acts against the planet's projectile motion just as much as it acted with it before. When the planet has got round to *a*, its projectile force is as much diminished from its mean state as it was augmented at *g*; and thus the sun's attraction being more than sufficient to keep the planet from going off at *a*, it describes the same orbit over again by the virtue of the same forces or powers. A double projectile force will always balance a quadruple power of gravity. Let the planet at *a* have twice as great an impulse from thence towards *x* as it had before; that is, the same length of time that it was projected from *a* to *v*, as in the last example; let it now be projected from *a* to *w*, and it will require four times as much gravity to retain it in its orbit; that is, it must fall as far from *a* to *r* in the time that the projectile force would carry it from *a* to *c*, otherwise it would not describe the curve *a t*, as is evident from

the figure. But in as much as the planet moves from a to c, in the higher part of its orbit, it moves from f to g, or from g to j, in the lower part thereof; because from the joint action of these two forces, it must always describe equal areas in equal times throughout its annual course. These areas are represented by the triangles $a\ y\ c$, &c., whose contents are equal to one another from the properties of the ellipse.

The *Earth* we inhabit must now be examined; its motions with reference to the occurrence of day and night, the phenomena of the seasons, &c., will readily be understood. Its mean distance from the sun is 23984 times its own semi-diameter; so that it is nearly 95 millions of miles distant from that luminary. It performs its mean sidereal revolution in 365.2563612 mean solar days, or 365 days, 6 hours, 9 minutes, 9 seconds, 6: but the time employed in going from one equinox to the same again, or from one tropic to the same again (whence called the tropical revolution), is only 365.2422414 mean solar days, or 365 days, 5 hours, 48 minutes, 49 seconds, 7.

The axis of the earth is inclined to the pole of the ecliptic, at an angle which, at the commencement of the present century, was 23° 27′ 56″ 5: which angle is called the obliquity of the ecliptic. It is observed to decrease at the rate of 0″, 4755 in a year. But this variation is confined within certain limits, and cannot exceed 2° 42′.

This angle is also subject to a periodical change, called the nutation; depending principally on the place of the moon's node: whereby the axis of the earth appears to describe a small ellipse in the heavens.

The intersection of the equator with the ecliptic is not always in the same point; but is constantly retrograding or receding contrary to the order of the signs. Consequently the equinoctial points appear to move forward on the ecliptic; and whence this phenomenon is called the precession of the equinoxes. The quantity of this annual change, caused by the action of the sun and moon, and which is called the luni-solar precession, is 50″.41; from which we must deduct the direct motion caused by the planets, equal to 0″.31: and the difference, or 50″.10 is the general precession in longitude. It is subject to a small secular variation. A complete revolution of the equinoxes is performed in 25.868 years.

A mean solar day, as adopted by the public in this country, is the time employed by the earth in revolving on its axis, as compared with the sun, supposed to move at a mean rate in its orbit, and to make 365.2425 revolutions in a mean Gregorian year. But the mean solar day, adopted by astronomers, is founded on the assumption that the sun makes only 365.2422414 revolutions in a mean Gregorian year. It is divided into 24 mean solar hours; and these are again subdivided into mean solar minutes and seconds.

The apparent day is the time employed by the earth in revolving on its axis, as compared with the apparent place of the sun. This day is also divided into 24 apparent hours; which are again subdivided into apparent minutes and seconds. This mode of reckoning is still used by the public in many parts on the continent; and is frequently referred to by the practical astronomer on various occasions. In fact, the apparent culmination of the sun is the commencement of the astronomical day to every practical astronomer; and in most ephemerides the computations are made in apparent time.

The astronomical year is divided into four parts, determined by the two equinoxes and the two solstices. The interval between the vernal and autumnal equinoxes is (on account of the eccentricity of the earth's orbit, and its unequal velocity therein) nearly eight days longer than the interval between the autumnal and vernal equinoxes. These intervals were, in 1801, nearly as follow:—

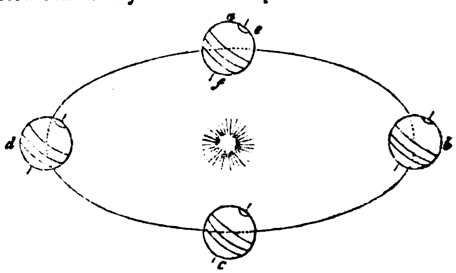
	D.	H.	M.	D.	H.	M.
From the vernal equinox to the summer solstice	= 92	21	50	= 186	11	34
From the summer solstice to the autumnal equinox	= 93	13	44			
From the autumnal equinox to the winter solstice	= 89	16	44	= 178	18	17
From the winter solstice to the vernal equinox	= 89	1	33			
				7	17	17

The figure of the Earth is that of an oblate spheriod; the axis of the poles being to the diameter of the equator as 304 to 305.

The mean diameter of the Earth is about 7916 miles: its equatorial diameter is 7924 miles, and its polar diameter 7898 miles.

As a necessary consequence from this circumstance, the degrees of latitude increase in length as we recede from the equator to the poles. But different meridians under the same latitude present different results; the general fact however is well ascertained.

The peculiar phenomena of the *seasons*, to which we may now call the reader's attention, are occasioned by the annual motion of the earth in its orbit. To understand this, we must bear in mind that the axis of the earth is inclined to the plane of its orbit, and that it always keeps parallel to itself, or is directed constantly to the same point of the heavens.

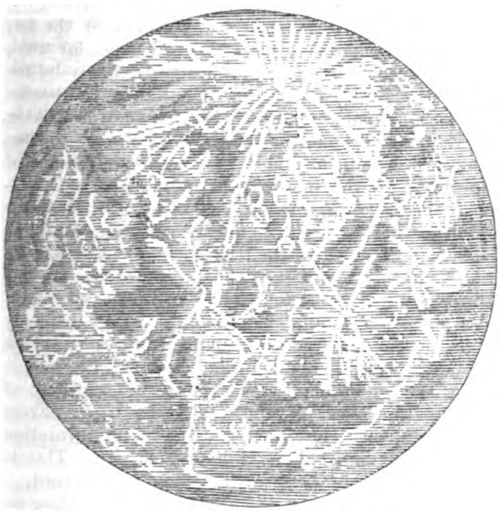


Let the accompanying figure represent the earth in different parts of its elliptic orbit. In the spring, the circle which separates the light from the dark side of the globe, called the terminator, passes through the poles, as appears in the position a. The earth, then, in its diurnal rotation about its axis, has every part of its surface as long in light as in shade; therefore the days are equal to the nights all over the world; the sun being at that time vertical to the equatorial parts of the earth. As the earth proceeds in its orbit, and comes into the position b, the sun becomes vertical to those parts of the earth under the tropic, and the inhabitants of the northern hemisphere will enjoy summer on account of the solar rays falling more perpendicularly

upon them; they will also have their days longer than their nights, in proportion as they are more distant from the equator; and those within the polar circle will have constant daylight. At the same time the inhabitants of the southern hemisphere have winter, their days being shorter than their nights, in proportion as they are farther from the equator; and the inhabitants of the polar regions will have constant night. The earth then continues its course to the position c, when the terminator again passes through the poles, and the days and nights are equal. After this the earth advances to the position *d*, at which time the inhabitants of the northern hemisphere have winter, and their days are shorter than their nights.

In summer, when the earth is at *b*, the sun is farther from it than in winter, and in fact, the disc of the sun appears longer in the winter than in the summer. The difference of heat is not owing to the sun's being nearer to us, or more remote, but to the degree of obliquity with which its rays strike any part of the earth. (See Heat and Sun.)

The *moon* is the constant attendant of the earth, and revolves around it in 27 days, 7 hours; but the period from one new or full moon to another, is about 29 days 12 hours. She is the nearest of all the heavenly bodies; being only about two hundred and forty thousand miles distant from the earth. She is much smaller than the earth; being only about 2160 miles in diameter.

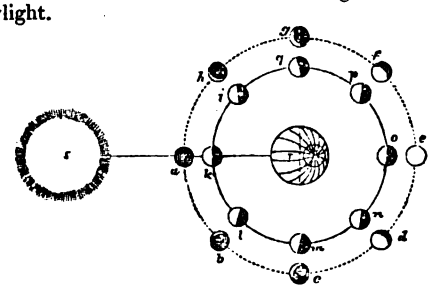


The surface of the moon when viewed with a telescope, presents an interesting and variegated aspect; being diversified with mountains, valleys, rocks, and plains, in every variety of form and position. Some of these mountains form long and elevated ridges, resembling the chains of the Alps and the Andes; while a variety of others, of a conical form, rise to a great height, from the middle of level plains, somewhat resembling the Peak of Teneriff. But the most singular feature of the moon is, those circular ridges and cavities which diversify every portion of her surface. A range of mountains of a circular form, rising three or four miles above the level of the adjacent districts, surrounds, like a mighty rampart, an extensive plain; and, in the middle of this plain or cavity, an insulated conical hill rises to a considerable elevation. Several scores of these circular plains, most of which are considerably below the level of the surrounding country, may be perceived with a good telescope, on every region of the lunar surface.

The preceding view of the moon's disc is taken from Russel's great map, and will furnish a tolerable notion of its rugged and unequal surface as seen through a telescope.

By the observations made by Dr. Herschel, in November, 1779, and the four following months, we learn that the altitude of the lunar mountains has been very much exaggerated. His observations were made with great caution, by means of a Newtonian reflector, 6 feet 8 inches long, and with a magnifying power of 222 times, determined by experiment; and the method which he made use of to ascertain the altitude of those mountains, which during that time he had an opportunity of examining, seems liable to no objection. The rock situated near *Lacus Niger*, was found to be about one mile in height, but none of the other mountains, which he measured, proved to be more than half of that altitude; and Dr. Herschel concludes that, with a very few exceptions, the generality of the lunar mountains do not exceed half a mile in their perpendicular elevation.

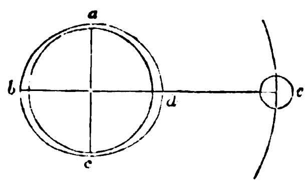
To Dr. Herschel we are also indebted for an account of several burning volcanoes, which he saw at different times in the moon. In the 77th vol. of the *Phil. Trans.* he says, "I perceive three volcanoes in different places of the dark part of the new moon. Two of them are nearly extinct; or, otherwise in a state of going to break out. The third showed an actual eruption of fire, or of luminous matter." On the next night, Dr. Herschel saw the volcano burn with greater violence than on the preceding evening. He considered the eruption as resembling a small piece of burning charcoal when it is covered by a thin coat of white ashes, which frequently adhere to it, when it has been some time ignited, and it had a degree of brightness, about as strong as that with which such a coal would be seen to glow in faint daylight.



The phases of the moon, as they appear at eight different points of her orbit, are represented in the accompanying figure, where *s* represents the sun, the earth being in the centre, and *a b c*, &c., the moon's orbit. When the moon is at *k*, in conjunction with the sun, her dark side being entirely towards the earth, she will be invisible, as at *a*, and is then called the new moon. When she comes to her first octant at *i*, a quarter of her enlightened hemisphere will be turned towards the earth, and she will then appear horned, as at *h*. When she has run through the quarter of her orbit, and arrived at *q*, she shows us the half of her enlightened hemisphere, as at *g*, when it is said she is one half full. At *p* she is in her second octant, and by showing us more of her enlight-

ened hemisphere than at *g*, she appears gibbous. At her opposition at *o*, her whole enlightened side is turned towards the earth, when she appears round as at *e*, and she is said to be full; having increased all the way round. On the other side she decreases again all the way from *e* to *a*; thus, in her third octant, part of her dark side being turned towards the earth, she again appears gibbous. At *m* she appears still farther decreased, showing again exactly one-half of her illuminated side. But when she comes to her fourth octant, she presents only a quarter of her enlightened hemisphere, and again appears horned. And at *a*, having now completed her course, she again disappears, and becomes a new moon again, as at first.

The *Tides* form an exceedingly interesting part of the subject of physical astronomy. The ocean covers more than half the globe; and this large body of water is in continual motion, ebbing and flowing alternately, that is, if the tide be supposed at high water mark, it will, after a short period, subside, and flow back for about six hours, when it will be at low water mark. The time of high water, however, is not always the same, but is about three-quarters of an hour later each succeeding day, for near thirty days, when it begins as before. Thus we may suppose at a certain place, it is high water at three o'clock in the afternoon on the day of new moon; the next day it will be high water at three-quarters of an hour after three, the day following at half-past four, and so on till the next new moon, when it will be again high water at three. This answers to the motion of the moon; for she rises every day about three-quarters of an hour later than the preceding one; and thus completes her revolution round the earth in about thirty days.



According to the Newtonian principle of attraction, these phenomena are thus explained. The waters at *d*, on the side of the earth next the moon *e*, are more attracted than the central parts *a c*, and these again move more than the waters on the opposite side at *b*, therefore the distance between the earth's centre and the waters on its surface under and opposite the moon will be increased. To explain this more fully, it should be borne in mind, that though the earth's diameter bears a considerable proportion to its distance from the moon, yet this diameter is nothing when compared to the earth's distance from the sun, consequently the difference of the sun's attraction on the sides of the earth opposite to him will be far less than the difference of the moon's attraction on the sides opposite to her; therefore the moon must raise the tides higher than they could be by the sun. Sir Isaac Newton has determined that the influence of the sun in this case is three times less than that of the moon. The tides, then, are properly the joint production of the sun and moon; or, in fact, there are two tides, a solar and a lunar, whose effects are joint or opposite, according to the situation of the bodies by which they are affected. When the sun and moon act together, as at new and full moon, the flux and reflux become considerable; and are called spring tides. But when one tends to elevate the waters, and the other to depress them, as at the moon's first and third quarters, then the flux and reflux will be diminished; these are called neap tides.

The sun being farther from our hemisphere in March and September, than in February and October, is the cause why the greatest tides happen a little before the vernal, and a little after the autumnal equinox.

When the moon is in the equator, the tides are equally high in both parts of the lunar day; but as she declines towards either pole, the tides are alternately higher or lower in northern or southern latitudes. The tides are so retarded in their passage through channels, and so affected by capes and headlands, as to happen variously at different places. The tide raised in the German Ocean, when the moon is three hours past the meridian, takes three hours to arrive at London Bridge. Lakes have no tides, because every part is attracted alike. The Mediterranean and Baltic seas have but small elevations on account of the narrowness of the inlets by which they communicate with the ocean.

Having examined the phenomena of the tides in connection with the attractive influence of the moon, it will now be advisable to observe the effects of that body when its orbit or path brings it between our planet and the sun, or vice versa, in which case an *eclipse* is produced.

Eclipses, especially of the sun, have always been considered as events of the most portentous kind. Isaiah, and others of the sacred writers, speak of them as indicative of the wrath of the Almighty. Homer, Pindar, Pliny, and many others of the ancients, also make mention of them in a similar way; and it is used to be noticed, more particularly by the superstitious, that an eclipse was often accompanied by a national calamity, or an occurrence of a striking nature, the malevolent effects of which were to continue, for the sun, as many years as the eclipse lasted hours, and for the moon as many months. Dionysius of Halicarnassus remarks, that both at the birth and death of Romulus there was a total eclipse of the sun, during which the darkness was as great as at midnight. It is also said that there was a solar eclipse on the day the foundation of Rome was laid.

An eclipse of the moon is mentioned by Ptolemy to have been observed by the Chaldeans at Babylon 720 years before the birth of our Saviour; the middle of the eclipse reducing the time to the meridian of Paris, was 6 hours, 48 minutes, March 19th. From this eclipse it is determined that the mean revolution of the moon is 27 days, 7 hours, 43′ 5″. This is considered the first eclipse of the moon on record.

Thales rendered himself famous by foretelling an eclipse of the sun; he, however, only predicted the year in which it would happen, and this he was probably enabled to do by the Chaldean Saros, a period of 223 lunations. This eclipse is rendered remarkable by its happening just as the armies under Alyattes, king of Lydia, and Cyaxeres the Mede, were engaged; and being regarded by each party as an evil omen, inclined both to make peace: it has been clearly proved that this eclipse occurred 610 years before Christ, September 30. Xenophon observes, that the king of the Persians laid siege to the city of Larissa at the time the empire was taken from the Medes, but was not able by any means to make himself master of it; finally, a cloud coming over the sun made it disappear, so that the hearts of the inhabitants failed, and the city was taken. This cloud

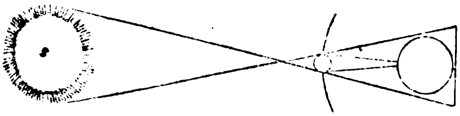
was, no doubt, the moon eclipsing the sun; for it appears that Cyrus finished the reduction of the Median empire, B.C. 547, in which year there was a great solar eclipse, the centre of which crossed the Tigris, not far from the place where Larissa was situated.

It is by a lunar eclipse that a mistake has been found in the Christian era; for it is well known that Christ was born when Herod was king of Judea; and Josephus affirms, that just before the death of this Herod there was an eclipse of the moon on the night between the 12th and 13th of March: but it has been clearly proved that this eclipse happened on the fourth year before what is considered the Christian era; wherefore this era ought to be carried back three years at least. The darkness that occurred at our Saviour's crucifixion, and which continued three hours, cannot be attributed to an eclipse of the sun, the Passover being kept at the time of full moon: had even the two luminaries been in conjunction, the darkness could only have lasted four or five minutes, owing to their apparent diameters being so nearly equal. Dionysius, a judge of Areopagus, being at Heliopolis, and observing this preternatural phenomenon, cried out, that "Nature was either dissolving, or the God of nature suffering." He afterwards embraced the Christian faith, and suffered martyrdom for the truth of it.

In China there is a tribunal of astronomy, the business of which is to calculate eclipses, and to present their types to the emperor and mandarins some months before they occur, with an account of the part of the heavens where they will happen, and how many digits the luminary will be eclipsed. When an eclipse is announced, preparation is made at court for the observance of it; as soon as it begins, a *blind man* beats a drum, upon which the mandarins and great officers mount their horses, and assemble in the great square of the palace.

An eclipse happened during Lord Macartney's embassy to China, which kept the emperor and his mandarins the whole day devoutly praying the gods that the moon might not be eaten up by the great dragon which was hovering about her: the next day a pantomime was performed, exhibiting the battle of the dragon and the moon, and in which two or three hundred priests, bearing lanterns at the end of long sticks, dancing and capering about, sometimes over the plain, and then over chairs and tables, bore no mean part.

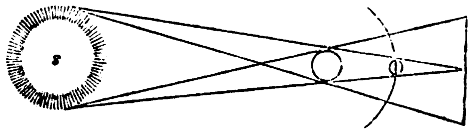
From this brief view of the early history of eclipses, we may now by the aid of an engraving illustrate the cause of these singular phenomena.



The sun at *s* is seen to have its light intercepted in its passage to the larger circle, on the right side of the figure by the moon's disc, which falls intermediate to those bodies. Now, in consequence of this arrangement of the sun, earth, and moon, an eclipse must occur. If the orbit of the moon was parallel to that of the earth, this exclusion of the sun's rays would happen on each succeeding month; but as her nodes are continually changing, annular eclipses of the sun which really arise from the moon, are of comparatively rare occurrence.

An annular eclipse is *central*, but not *total*; for the moon being at this time in her *apogee*, or at her greatest distance from the earth, her shadow terminates at some distance from its surface. Even when nearest to the earth, or in her *perigee*, her shadow never falls upon more than 180 miles of the surface. During total eclipses of the sun, small stars become visible; and at the period of the great solar eclipse in 1820, at which time 10½ digits out of the 12 were obscured, the planets Mercury and Venus could be seen by the naked eye.

By a reference to the engraving, it will be seen that an eclipse of the sun can only last for a short time, as the penumbra or shadow projected on the earth is smaller than the moon itself; but in the next form of eclipse, for which we shall require another figure, the darkness may last for a much longer period.



The sun is still in the same situation as before, but the earth and moon have changed places, so that an inhabitant of the latter body would see the earth obscuring the sun's rays. It will thus be obvious, that what we call an eclipse of the moon, is in reality an eclipse of the solar light.

A total eclipse of the moon can only happen when that body is exactly in the node at the time of opposition, in which case it remains enveloped in the shadow of the earth two hours; and as it passes through the centre of the shadow, which is considerably darker than near the edges, the moon is more completely obscured.

A great solar eclipse, visible in England, will take place 15th May, 1836, when 11° 18′ will be covered.

Another considerable eclipse of the sun will occur 15th March, 1858, when 11° 30′ will be hidden.

A still more remarkable eclipse of the sun will take place 19th August, 1887, when the whole of the disc will be covered excepting 2′.

A total eclipse, without continuance, will occur 3d February, 1916. The apparent diameters will coincide, and for an instant there will be a total concealment of the sun's light. This eclipse will be the greatest that will be visible in England till after the year of our Lord 2000.

To complete the above view of the solar system, it will be necessary now to examine another class of bodies, differing very considerably in their arrangement from the planets. These are the *comets*; they generally appear attended by a nebulous light, either surrounding them as a comma, or stretched out to a considerable length as a tail; and they sometimes seem to consist of such light only. Their orbits are so eccentric, that in their remoter situations, the comets are no longer visible to us, although at other times they approach much nearer to the sun than any of the planets; for the comet of 1680, when in its perihelion, was at the distance of only one-sixth of the sun's diameter from its surface. Their tails are often of great extent, appearing as a faint light, directed always towards a point nearly opposite to the sun: it is quite uncertain of what substance they consist; and it is difficult to determine which of the

conjectures respecting them can be considered as the least improbable: it is possible that, on account of the intense cold to which the comets are subjected in the greatest part of their revolutions, some substances, more light than any thing we can imagine on the earth, may be retained by them in a liquid, or even in a solid form, until they are disengaged by the effect of the sun's heat. But we are still equally at a loss to explain the rapidity of their ascent; for the buoyancy of the sun's atmosphere cannot possibly be supposed to be adequate to the effect; and on the whole, there is, perhaps, reason to believe that the appearances are derived from some cause bearing a considerable analogy to the fluid supposed to be concerned in the effects of electricity. It is probable that the density of the nucleus, or the body of the comet itself, is comparatively small, and its attraction for the tail consequently weak, so that it has little tendency to reduce the tail, even if it consists of a material substance, to a spherical form; for since some comets have no visible nucleus at all, there is no difficulty in supposing the nucleus, when present, to be of a very moderate density, and perhaps to consist of the same kind of substance as constitutes the tail, or comma, in a state of somewhat greater condensation. If, therefore, it should ever happen to a planet to fall exactly in the way of a comet, of which there is but very little probability, it is to be supposed that the inconvenience suffered by the inhabitants of the planet might be merely temporary and local: the chances are, however, much greater, that a comet might interfere in such a manner with a planet, as to deflect it a little from its course, and retire again without coming actually into contact with it.

The number of comets is very much greater than that of the planets which move in the vicinity of the sun. From the reports of former historians, as well as from the observations of late years, it is ascertained that more than four hundred and fifty have been seen previous to the year 1771; and when the attention of astronomers was called to this subject, by the expectation of the return of the comet of 1759, no fewer than seven were observed in the course of as many years. From this circumstance, and the probability that all the comets recorded in ancient authors, were of considerable apparent magnitude, while the smaller were overlooked; it is reasonable to conclude that the number of comets is considerably beyond any estimate that might be made from the observations we now possess. But the number of comets whose orbits are settled with sufficient accuracy to ascertain their identity when they may appear again, is no more than fifty-nine, reckoning as late as the year 1771. The orbits of most of these are inclined to the plane of the ecliptic in large angles, and the greater number of them approached nearer the sun than the earth ever does. Their motions in the heavens are not at all in the order of the signs, or direct, like those of the planets; but the number whose motion is retrograde, is nearly equal to that of those whose motion is direct.

The analogy between the periodical time of the planets, and their distances from the sun, discovered by Kepler, takes place also in the comets. Hence, the mean distance of a comet from the sun may be found by comparing its period with the time of the earth's revolution round the sun: thus, the period of the comet that appeared in 1531, 1607, 1682, and 1759, being about seventy-six years, its mean distance is found by this proportion: as the square of one year, the earth's periodical time, is to 5776 the square of 76, the comet's periodical time; so is 1,000,000 the cube of 100, the earth's mean distance from the sun, to 5,776,000,000 the cube of the comet's mean distance, the cube root of which is 1794, the mean distance itself, in such parts as the mean distance of the earth contains 100. If the perihelion distance of this comet, 58, be taken from 3588, double the mean distance, we shall have the aphelion distance 3530 of such parts as the distance of the earth contains 100; and this is little more than 35 times the distance of the earth from the sun. By a like method, the aphelion distance of the comet of 1680, comes out 138 times the mean distance of the earth from the sun, supposing its period to be 575 years; so that this comet in its aphelion, goes to more than 14 times the distance from the sun that Saturn does.

Comets, in describing their elliptic orbits round the sun, have been found to be disturbed by the action of the larger planets, Jupiter and Saturn; but the great eccentricity of their orbits makes it impossible, in the present state of mathematical science, to assign the quantity of that disturbance for an indefinite number of revolutions, though it may be done for a limited portion of time, by considering the orbit as an ellipsis, the elements of which are continually changing. This method was suggested by La Grange, and is followed in the *Mécanique Céleste*. Dr. Halley, when he predicted the return of the comet of 1682, took into consideration the action of Jupiter, and concluded that it would increase the periodic time of the comet a little more than a year; he therefore fixed the time of the reappearance to the end of the year 1758, or the beginning of 1759. He professed, however, to have made this calculation hastily, or, as he expresses it, *levi calamo*.—(*Synopsis of the Astronomy of Comets.*)

The effects both of Jupiter and Saturn, on the return of the same comet, were afterwards calculated more accurately by Clairaut, who found that it would be retarded 511 days by the action of the former planet, and 100 by the action of the latter; in consequence of which, the return of the comet to its perihelion would be on the 15th of April, 1759. He admitted, at the same time, that he might be out a month in his calculation. The comet actually reached its perihelion on the 13th of March, just thirty-three days earlier than was predicted; affording, in this way, a very striking verification of the theory of gravity, and the calculation of disturbing forces. The same comet may be expected again about the year 1835.

In some instances, the effects which the planets produce on the motion of comets, are far more considerable than in this example. A comet which was observed in 1770, had a motion which could not be reconciled to a parabolic orbit; but which could be represented by an elliptic orbit of no great eccentricity, in which it revolved in the space of five years and eight months. This comet, however, which had never been seen in any previous revolution, has not been seen in any subsequent one. On tracing the path of this comet, Mr. Burkhardt found that, between the years 1767 and 1770, it had come very near to Jupiter, and had done so again in 1779. He therefore conjectured that the action of Jupiter may have so altered the original orbit, as to render the comet for a time visible from the earth; and that the

same cause may have so changed it, after one revolution, as to restore the comet to the same region in which it had formerly moved. This, if a true conjecture, is the greatest instance of disturbance which has yet been discovered among the bodies of our system, and furnishes a very happy as well as an unexpected confirmation of the theory of gravity.

Though the comets are so much disturbed by the action of the planets, yet it does not appear that their re-action produces any sensible effect. The comet of 1770 came so near to the earth as to have its periodical return accelerated by two days; two hundred and forty-six, according to La Place; and if it had been equal in mass to the earth, it would have augmented the length of the year by not less than two hours and forty-eight minutes. It is certain that no such augmentation took place, and therefore that the disturbing force by which the comet diminished the gravity of the earth is insensible, and the mass of the comet, therefore, less than 1-500th of the mass of the earth. The same comet also passed through the middle of the satellites of Jupiter. Hence, it is reasonable to conclude, that no material, or even sensible alteration, has ever been produced in our system by the action of a comet.

M. Fatio has suggested that some of the comets have their nodes so very near the annual orbit of the earth, that if the earth should happen to be found in that part next the node, at the time of a comet's passing by, as the apparent motion of the comet will be incredibly swift, so its parallax will become very sensible; and the proportion thereof to that of the sun may be given; so that such transits of comets will afford the best means of determining the distance of the earth and sun.

The only other comet which it will be advisable to notice in our present article is that of Biela, the one which is now (November, 1832) generally expected. Lord Byron, whose writings bespeak more of true poetry than scientific knowledge, characterises one of these "wandering planets" as

> "A *pathless* comet and a curse,
> The menace of the universe."

We mention the singular mistake implied in the above line, as a similar one has been committed by many others as well as the noble poet. Now a reference to the comet of Biela will show that the path and period of a comet may be calculated on with great precision. It was particularly noticed by the astronomer from whom it takes its name, on the 27th of February, 1826, and on examining its elements in connection with the preceding comet, it was found that they must be one and the same. An anomaly however appeared in the period of revolution, which in one of its returns was completed in 2460 days, and in the other, 2469 days; this inequality was found to be owing to the action of the planet Jupiter, near which it had passed.

Proceeding onward, to the more distant regions of space, we come to the *fixed stars*. Prior to a notice of their classification, however, a few preliminary remarks will best explain their nature and arrangement.

The fixed stars are farther distant from the earth than the farthest of the planets; as we frequently find the fixed stars hid behind the most distant of those bodies; and they are supposed to have no parallax, which the planets have. It is inferred that the fixed stars are greater than our earth; for if that was not the case, they could not be visible at such an immense distance.

It is evident, also, that the fixed stars shine with their own light; for they are much farther from the sun than the remotest planet, and appear much smaller; but since, notwithstanding this, they are found to shine much brighter than such planet, it is evident they cannot borrow their light from the same source.

Astronomers divide the heavens into three regions; a northern and a southern hemisphere, and the zodiac. Stars of various magnitudes are seen in all these regions, and are classed into what are called constellations, or systems of stars, according as they lie near one another, so as to occupy those spaces which the figures of different sorts of animals would take up, if they were delineated on what appears to be the concave surface of the heavens. Those stars which the ancients could not bring into any particular constellation, they called unformed stars, but most of these are comprehended in the new constellations of the moderns.

This mode of dividing the stars into different constellations, serves to arrange them in such a manner that any particular star may be readily found in the heavens by means of a celestial globe, on which the constellations are so delineated as to put the most remarkable stars into those parts of the figures which may be most easily pointed out. This may be illustrated by a reference to the classification already alluded to.

Constellations of the Zodiac.

Constellations.	No. of Stars.	Principal stars and their magnitudes.	
Aries	66		
Taurus	140	Aldebaran	1
Gemini	85	Castor 1, Pollux	2
Cancer	83		
Leo	95	Regulus	1
Virgo	110	Spica Virginis	1
Libra	51	Zubenich Meli	2
Scorpio	44	Antares	1
Sagittarius	69		
Capricornus	51		
Aquarius	108	Scheat	3

The stars vary very materially in their apparent magnitude and number at different periods of time.

The first new star that we have any good account of, was discovered by Cornelius Gemma, in 1572, in the chair of Cassiopeia. It surpassed Sirius in brightness and magnitude; and was seen for sixteen months successively. At first, it appeared larger than Jupiter, and then it gradually diminished both in magnitude and lustre, until 1573, when it became invisible.

On the 13th of August, 1596, David Fabricius observed the stella Mira, in the neck of the whale; which has since appeared and disappeared periodically.

In the year 1600, William Jansenius discovered a changeable star in the neck of the swan; which, in time became so small as to be thought to disappear entirely; till the year 1657, when it recovered its former lustre and magnitude.

In the year 1604, Kepler and several of his friends saw a new star near the heel of the right foot of Serpentarius, so bright, that it exceeded any thing they had ever seen before; and they state, that it was every moment changing into some of the colours of the rainbow, except when it was near the horizon, at which time it was generally white. It surpassed Jupiter in magnitude. It disappeared between October 1605, and the February following, and has not been seen since that time.

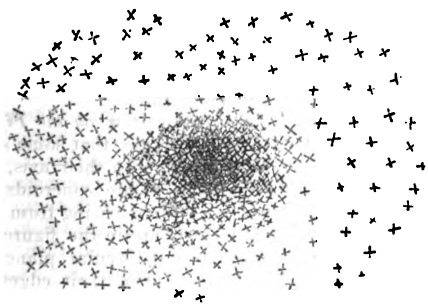
In July 1670, Hevelius discovered a new star, which was scarcely perceptible in October. In April following, it still retained its lustre, but wholly disappeared in August. In March 1672, it was seen again, but very small; and has not been visible since. It may be proper to add, that the star Algol, in the space of rather more than two days, changes from the second to the fourth magnitude.

M. Maupertuis, in his *Dissertation on the Figures of the Celestial Bodies*, is of opinion, that some stars, by their prodigious swift rotation on their axis, may not only assume the figures of oblate spheroids, but that by the great centrifugal force arising from such rotations, they may ultimately attain the figure of a mill-stone, or be reduced to flat circular planes, so thin, as to be quite invisible when their edges are turned towards us, as Saturn's ring is in such a position. But when very eccentric planets, or comets, go round any flat star in orbits much inclined to its equator, the attraction of the planets, or comets, in their perihelions must alter the inclination of the axis of the star; on which account it will appear more or less large and luminous, as its broad side is more or less towards us. And thus he imagines we may account for the apparent changes of magnitude and lustre of those stars, and likewise for their appearing and disappearing.

Dr. Herschel's success in examining the milky-way with his great instrument, induced him to turn his telescope to the nebulous parts of the heavens. Most of these yielded to a Newtonian reflector, of twenty feet focal distance, and twelve inches aperture; and he ascertained that they were composed of stars, or at least contained stars, and afforded very strong indications of their consisting of them entirely. "The nebulæ," says he, "are arranged into strata, and run on to a great length, and some of them I have been able to pursue, and to guess pretty well at their form and direction. It is probable enough that they may surround the whole starry sphere of the heavens, not unlike the milky-way, which undoubtedly is nothing but a stratum of fixed stars; and as this immense starry bed is not of equal lustre in every part, nor runs in one straight direc-

tion, but is curved, and even divided into two streams along a very considerable portion of it; we may likewise expect the greatest variety in the strata of the cluster of the stars and nebulæ. One of these nebulous beds is so rich, that in passing through a section of it in the time of only thirty-six minutes, I have detected no less than thirty-one nebulæ, all distinctly visible upon a fine blue sky. Their situation and shape, as well as condition, seem to denote the greatest variety imaginable. In another stratum, or perhaps a different branch of the former, I have often seen double and treble nebulæ variously arranged; large ones, with small seeming attendants; narrow, but much extended lucid nebulæ, or bright dashes; some of the shape of a fan, resembling an electric brush issuing from a lucid point; others of the cometic shape, with a seeming nucleus in the centre, or like cloudy stars, surrounded with a nebulous atmosphere; a different sort of orb again, containing a nebulosity of the milky kind, like those wonderful, inexplicable phenomena about Orionis; while others shine with a fainter mottled kind of light, which denotes their being resolvable into stars."

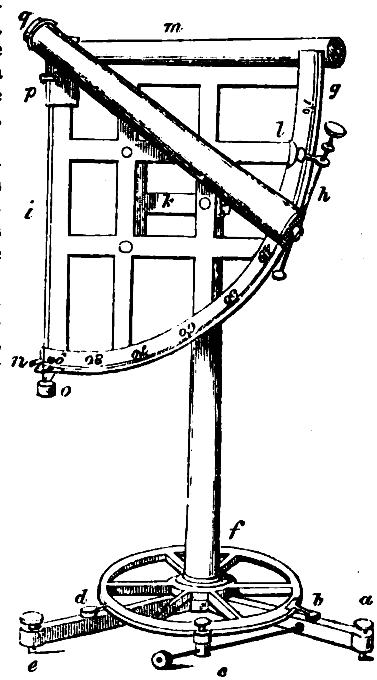
One of the remarkable nebulous appearances observed by Dr. Herschel, is delineated in the accompanying wood cut. It is taken from Orion, and does not of course come within the powers of a small telescope.



Huygens considered the view he had of this nebulosity as similar to that arising from a curtain being raised, and the observer piercing into an ocean of light, of which the waves were irregular.

The stars of the firmament are said to be fixed, because they have been generally observed to preserve the same distance from each other: they do not all appear to us of the same magnitude, whether they are really different in size one from the other, or whether they appear so to us in consequence of their different distances. It is probable that both these causes operate to display the fixed stars of such various magnitudes. Be this as it may, astronomers have agreed in distributing the fixed stars into six different classes, according to their relative magnitude, independent of those small stars which compose the white and brilliant spaces in the heavens, which are denominated nebulæ, and that bright band which extends across our hemisphere, and which from its lucid appearance is termed the milky-way. Those which are distinctly visible are fewer in number than might be supposed. The British catalogue, which, besides the stars visible to the naked eye, includes a great number which cannot be seen without the assistance of a telescope, contains no more than three thousand in both hemispheres. The number of stars discoverable, in either hemisphere, by the naked eye, is not above a thousand. From what we are able to judge by computation and observation, it is concluded that none of the fixed stars can be at a less distance than 32,000,000,000,000 of miles from us, which is farther than a cannon-ball would fly in 7,000,000 of years.

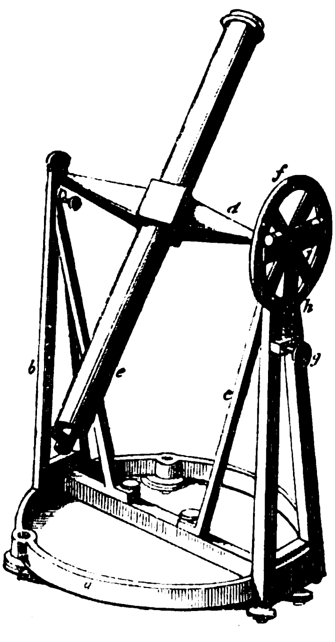
In pursuance of our plan as already arranged, we must now proceed to the subject of *practical astronomy*. Under this head it will be necessary in the first instance to describe the simplest sort of astronomical instruments, commencing with the *quadrant*.



This is a very important, and at the same time, a cheap piece of apparatus, though in large observatories it is but little employed. It is shown in the engraving, mounted on a circular pillar *f*, which is supported by a tripod, *a e*, resting on three foot-screws. The quadrant, *m*, the pillar, and the horizontal circle, all revolve round a vertical axis. A telescope is placed on the horizontal radius, and is directed to a meridian mark, previously made on some distant object for placing the plane of the instrument in the meridian, and also for setting the zero, or beginning of the scale, exactly horizontal. This is sometimes done by a level, instead of a telescope, and sometimes by a plumb-line, *i*, suspended from near the centre, and brought to bisect a fine dot made on the limb, where a microscope, *n*, is placed, to examine the bisection. The weight or plummet, at the end of the plumb-line, is suspended in a small cistern of water, *o*, which keeps it from being agitated by the air. A similar dot is made for the upper end of the plumb-line, upon a piece of brass, adjustable by a screw, *p*, in order that the line may be exactly at right angles with the telescope, when it is placed at 0°. The central part of the frame of the quadrant is screwed to a piece of brass, *k*, by three screws, and this piece is again screwed by three other screws at the top of the pillar, *f*. By means of the three first screws, the plane of the quadrant can be placed exactly parallel to the vertical axis, and by the other screws the telescope can be placed exactly perpendicular to it. The nut of the delicate screw, *h*, is attached by an universal joint to the end of the telescope. The collar for the other end is attached by a similar joint to a clamp, *l*, which can be fastened to any part of the limb. A similar

clamp-screw and slow motion is seen at *c*, for the lower circle.

In using this instrument, the axis of the telescope is adjusted to a horizontal line, and the plane of the quadrant to a vertical line, by the means already mentioned. The screw of the clamp, *l*, is then loosened, and the telescope directed to the star whose altitude is required. The clamp-screw being fixed, the observer looks through the telescope, and with the nut of the screw *h*, he brings the telescope into a position where the star is bisected by the intersection of the wires in the field of the telescope. The divisions are then to be read off upon the vernier, and the altitude of the star will be obtained. By means of the horizontal circle, *d*, *b*, all angles in the plane of the horizon may be accurately adjusted.



The *transit instrument* is of great use to the astronomical observer. It consists of a telescope, moveable in the plane of the meridian upon a horizontal axis, for the purpose of observing the precise instant when any celestial object passes the meridian.—One of Mr. Troughton's portable transit instruments is represented in the accompanying figure, where *e* is an achromatic telescope, firmly fixed by the middle to a doubly conical and horizontal axis, *d*, the pivots of which rest on angular bearings called Y's, at the top of the standards, *b*, *c*, rendered steady by oblique braces fastened to the central part of the circle *a*. The axis has two adjustments, one for making it exactly level, and the other for placing the telescope in the meridian. A graduated circle, *f*, is fixed to the extremity of the pivot which extends beyond one of the Y's, and the two radii that carry the verniers, are fitted to the extremity of the pivot in such a way as to turn round independent of the axis. The double verniers have a small level attached to them, and a third arm, *h*, which is connected with the standard by means of a screw, *g*. If the verniers are placed, by means of the level, in a true horizontal position, when the axis of the telescope is horizontal, and the arm *h* screwed to the standard, the verniers will always read off the inclination of the telescope, and will enable the observer to point it to any star, by means of its meridian altitude. The whole instrument rests on three foot-screws passing into the circle *a*. The telescope has a diagonal eye-piece for observing stars near the zenith, and in the field of view there are several parallel vertical wires crossed at right angles with a horizontal one.

In order to fix the transit instrument exactly in the meridian, the observatory clock should be previously regulated to sidereal time, by means of corresponding or equal altitudes of the sun or a star, taken before and after they pass the meridian, by small quadrants or circles, or by a good sextant. The axis of the transit is then to be placed horizontal, by means of a spirit level which accompanies the instrument, and the greatest care must be taken that the axis of vision describes in the heavens a great circle of the sphere.

The instruments we have now been describing, though of considerable value to the practical astronomer, are unfitted for some of the most important observations he will be called upon to make. On this account we proceed to describe a very important piece of apparatus, combining in itself a variety of instruments, and one that is well fitted for a private observatory.

When a simple telescope mounted on a stand, is elevated to view any heavenly body at the moment of its meridian passage, the observed body appears to pass horizontally across the field of view, but in any other situation to the east or west of the meridian, the apparent passage of the body through the field of view is in an oblique direction, and the more so the greater the declination towards the visible pole, and also the greater the distance from the meridian line. Hence, the motion of the simple telescope, which moves in a circle parallel to the horizon, when turned round on its vertical axis, will never coincide with the motion of a heavenly body that moves either in the equator, or in a circle parallel to it; unless indeed the observer could stand at one of the poles, in which case the equator would become the horizon, and circles of altitude would be also circles of declination. But no observer can be so circumstanced. He may, however, incline the axis of motion of his telescope, so as to be placed in the meridian, and exactly parallel to the earth's axis, and then when the field of view is directed to take in any heavenly body, the motion of the telescope round such axis, supposing it to be fixed, will attend the said body during the remainder of its path above the horizon. Accordingly we find Christopher Scheiner using a telescope mounted on a polar axis, in 1620, which was soon after the time that Galileo invented the simple dioptric telescope; and though Mullër contrived his torquet, a kind of portable equatorial, in 1544, yet the idea of Scheiner's polar axis most likely suggested to the modern instrument-makers the best principle on which an equatorial instrument, as well as the equatorial sector, ought to be constructed. By the use of Scheiner's contrivance, an observer could follow a star or other heavenly body through its diurnal arc, but it had no appendages to ascertain the place of the observed body, as to right ascension, declination, distance from the meridian, &c.; neither could the telescope be directed to a body invisible to the naked eyê.

Mr. Henry Hindley, an eminent clock-maker at York, was probably the first man who contrived and attached the different adjustable circles as companions to the telescope. Mr. Smeaton, in his paper on the *Graduation of Astronomical Instruments*, read before the Royal Society, November 17, 1785, states that Hindley contrived an instrument of the equatorial kind so early as 1741. This instrument had the equatorial plate, quadrant of latitude, and declination

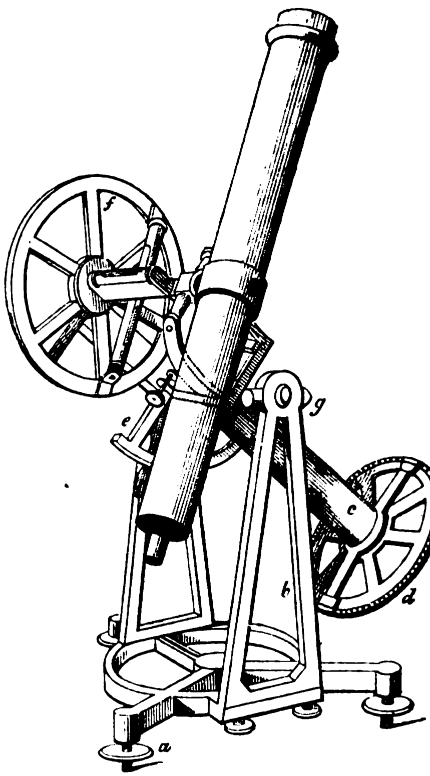
semi-circle indented at the circumference, and moved by worm-screws, containing fifteen threads each, all in action together.; which screws at the same time measured as micrometer screws, the angular motions. The telescope was of the refracting kind, and inverted the object viewed. "It staid with me," says Mr. Smeaton, "two years, in which time I showed it to all my mechanical and philosophical friends, amongst whom was Mr. Short, who afterwards published, in the *Philosophical Transactions*, an account of a portable observatory, but without claiming any particular merit for the contrivance."

Mr. Short placed his reflecting telescope over a system of graduated circles, and he has generally been considered as the first contriver of the equatorial instrument, though it appears evident from Mr. Smeaton's account that Hindley's instrument was somewhat prior to his.

We come now to Mr. Troughton, who constructed an equatorial instrument sufficiently large to be placed in an observatory for the purpose of making useful observations. This ingenious artist contrived many modifications of the instrument, but the portable equatorial instrument, invented by Mr. Fayrer, will require a more particular description, as its price will admit of its general use in private observatories. This instrument differs from its predecessors chiefly in these respects; it has no azimuth circle fixed in a permanently horizontal position; it has its equatorial circle divided into degrees and also into time, with two verniers reading at opposite points, one vernier reads to the accuracy of 30″ of space, and the other to 2″ of time; this circle has a long axis passing through a tube, so that it may be placed in a horizontal direction by its axis being placed firmly vertical, in which situation it becomes an azimuth circle; the telescope is fixed on the end of the axis of the declination circle. This position allows any elevation of the telescope that may be required, and keeps the observer's eye at a distance from the other parts of the instrument, but injures the uniformity of the appearance of the instrument as a whole; the levels are applied, one on the common axis of the telescope and declination circle, and the other at right angles thereto, as a chord to the declination circle; and lastly, the declination circle is complete, with opposite verniers reading to about twenty or thirty seconds, according to the dimensions of the graduated circles.

From such a construction it is easy to perceive that this little instrument possesses the advantage of having its telescope reversed as well as its circles, with respect to the opposite verniers, which property greatly ensures the accuracy of the adjustments. After these previous remarks, it will suffice to give a brief detail of the parts of this instrument, as represented in the accompanying figure.

The adjustment screws are shown at *a*. The triangular frames, *b*, are fixed firmly to the circular stand, and support the pivots of the horizontal axis, round which the tube *c* moves. At the summit of the triangular frame *b*, is an adjustable or sliding part, like that of a transit instrument, by which the telescope may be adjusted in the meridian, when previously placed nearly so by the feet. The graduated circle, which may be either an equatorial or azimuth circle, accordingly as it is inclined or vertical, has a steel axis nicely fitted to revolve in the tube in any required position with respect to the horizon; but the double vernier bar is in this case fast to the inferior end of the tube.



The posterior pivot of the horizontal axis, borne by the triangular bars, projects, and has firmly attached to it the quadrantal piece, *e*, partly hidden from sight in our view of the instrument; this quadrantal piece is graduated, and reads by a vernier as minutely as the other circles; it serves to set the equatorial axis parallel to the earth's axis, in which situation it may be clamped fast, as well as in a vertical, or indeed in any other position, by a clamping-screw out of sight in the present position, applying to the quadrantal arch; the declination circle is shewn at *f*, with its horizontal axis resting on a pair of vertical supports, carried by the upper end of the polar axis, that passes through the tube *c*, so that, when the telescope, attached to the axis of the declination circle, has any horizontal or rather oblique motion, the other circle moves with it, and indicates the distance moved along the equator, or in a circle parallel to it. The double vernier bar is on the posterior place of the declination circle, and may therefore be viewed after an observation without danger of altering the position of the telescope. The level on the declination axis may be conveniently adjusted by turning the circle half round, and by making the bubble keep the middle of the tube in both situations, which may be done, partly by the screws *a*, and partly by the screws of rectification of the level itself; and zero of the declination circle may be put to zero on the verniers when the circle is truly placed in an horizontal position, in which situation also zero of the quadrant *e*, must coincide with the zero on its vernier. An instrument thus constructed, will possess all the va-

rious powers ascribed to a portable equatorial, combined with the other instruments.

We have now to furnish an account of the most important astronomical instrument which the ingenuity and mechanical skill of this country has produced; we allude to the *great circle* of Mr. Ramsden, which has been very fully described by Piazzi. It is represented in our Plate, ASTRONOMY, *fig.* 1. The vertical axis of this instrument is composed of various parts, which revolve together, and which may be considered, when firmly united, as one piece; at the lower end is a cone, I, inverted, the smallest diameter of which is five inches, where it is attached to the azimuth or horizontal circle with a series of conical radii, and the greatest diameter is 14.2, where it is fixed to the oblong stage of brass, A; which stage is further strengthened by suspension pieces, at the four corners. The azimuth circle is three feet in diameter, divided into 180° twice over, and each of the degrees again into ten subdivisions of 6′ each. The extreme inferior end of the axis, below the azimuth circle, is a small cone of hard steel. On the stage A, are fastened four strong brass pillars, indicated by the letters C C C C, and placed near the corners of the stage. Above the superior ends of these four pillars, is another stage, B, of similar dimensions, in the centre of which is a tube, which constitutes the upper pivot of the axis; at each side of the central tube of this upper stage, is an opening which nearly divides the stage in two, except at the middle and two extreme edges, which edges are made firm by lateral connecting pieces; the use of the open parts of the upper stage is to admit the object end of the telescope, to view stars near the zenith.

The two large pillars, each 7 feet high, and 4 inches diameter, ascending from marble bases on the floor of the observatory, and terminating with a large arch, which connects their superior ends, constitute a part of the superior support of the vertical axis; two similar pillars, omitted in the engraving, also rest on the marble base at right angles to the above. At the top of the arches, a cross or piece of four straight bars, is screwed to the four upper portions of the arches, and a hole in the centre of this uppermost cross piece receives the tubular pivot of the vertical axis. The lower support of the vertical axis consists of three concentric circles of iron, laid one over another on friction rollers; the uppermost of which bears the inferior pivot of the axis, and the other two have each an adjustable motion, one from east to west, and the other from north to south. These are moved by handles attached to fine screws, which screws acting as pressing points, move the large iron circles in their respective directions, when the axis is to be placed exactly perpendicular to a horizontal line drawn in any azimuth. M is a mahogany circle attached to the uppermost iron circle; on this circle of wood is placed a balustrade of metal, R R, composed of a superior and inferior large ring, each being three feet in diameter, connected by twenty cylindrical pillars, each of one inch diameter, and 13 inches high; this balustrade defends the azimuth circle, and serves to give either a slow or quick motion from it to the axis of the instrument, by means of the clamping mechanism, connected with an universal joint, of which the handle Q only is seen in the figure. The microscopic micrometer, N, which reads off the graduations of the azimuth circle, is also carried between two of the pillars of this balustrade, together with the subjoined reflector of silver for the illumination of the dividing marks of the azimuth circle: the field of view of the compound microscope contains but a very small space of the image of the divided limb; it was therefore found necessary, not only to mark every degree with ten successive Arabic numerals, and also each tenth space, with larger numerals of the Roman character, but also to insert points for discriminating the ten subdividing lines, which are counted 0, 1, 2, 3, &c., the distance between each of which, we have already said is 6′, therefore, the corresponding values are 0′, 6′, 12′, 18′, 24′, &c. up to a degree, as read without the aid of the micrometer.

The compound microscope, N, has the mechanism of the micrometer, in the point where the focus of the eye-glass, or perhaps we should rather say, where the united foci of the glasses of the compound eye-piece meet the image of the subdivisions of the limb, as formed in the tube by the object-lens; this mechanism is rather complex, and cannot be very clearly apprehended, perhaps, by a mere verbal description; it consists of two parallel horizontal plates of metal, having each an oblong hole along its middle, the upper one of brass and the lower of steel; the brass one is divided into ten spaces of each 1′, counted each way from zero, which is a point in the middle, and is moveable separately by the horizontal screw on the left hand; the steel plate carries a cross hair or wire, and is adjustable to the right or left by a screw of 70 threads per inch, which has a nut, as a head, divided into 60 equal parts, one of which parts corresponds to a second of a degree; this divided head is placed at the right hand of the microscope, so that one of the two screws cannot be mistaken for the other, and both may be held at the same time, and turned by the separate hands of an observer, if necessary. To prevent a loss of motion in the screw of divided head, or micrometer-screw, a spring of contrary pressure is applied in constant action, which makes the cross wire move backwards or forwards, without the loss of even a second, as counted on the divided head.

The microscopes have two adjustments, one for the object-lens to make the image fall distinctly on the micrometer's thread and scale, and another for the eye-piece to render this image clear to the eye; also the micrometer has two adjustments, one to adjust zero of the scale, under the eye-piece, to zero of the image of the divided limb: these two latter adjustments are effected by the different fixing screws, which are not seen in the figure. The circumscribing boundary of the circle, corresponding to the felley of a wheel, is formed of two separate rings, united in various equidistant points by parallel cylindrical pieces, so that the appearance of the compound piece is that of a circular ladder; a form which gives strength without any great addition to the weight. On the plane of one of these rings is firmly fixed a third circle, which contains the lines of graduation, which are but faintly seen in the figure. The central piece, or nave of the wheel, into which the spokes, or radii, are fast, is a segment of a cylinder of cast brass, nicely perforated in the middle, and the spokes are composed of eight metallic cones and the telescope, which passes through the nave and forms two more. The horizontal axis of this large circle, or wheel, as we have described it, is formed of a double cone, which is hollow throughout, and has pivots of hard steel at the extreme ends; it has four supports,

ASTRONOMY.

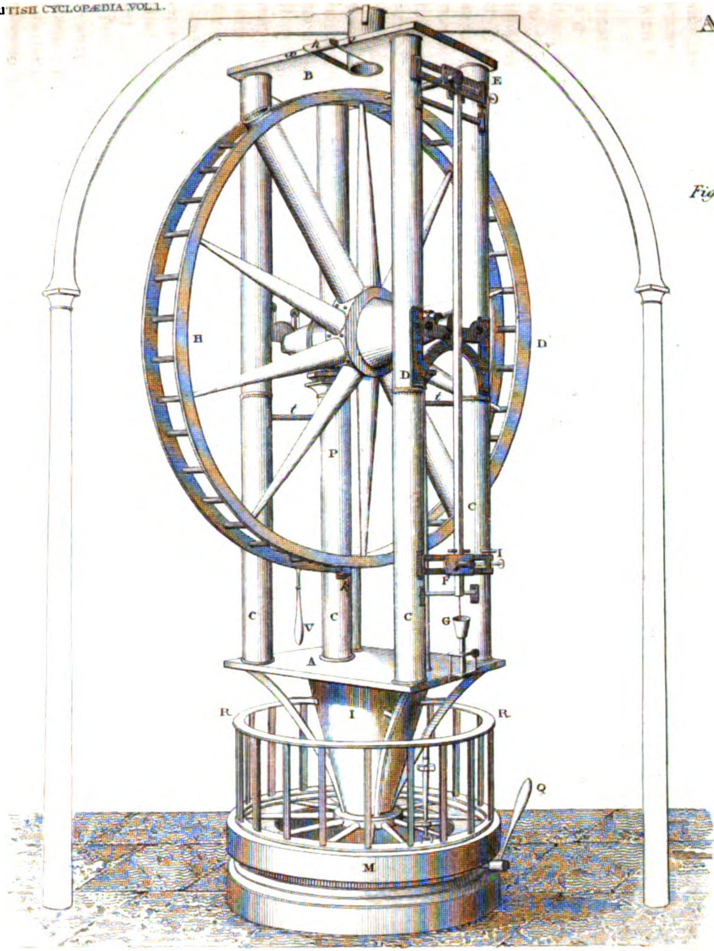

Fig. 2.

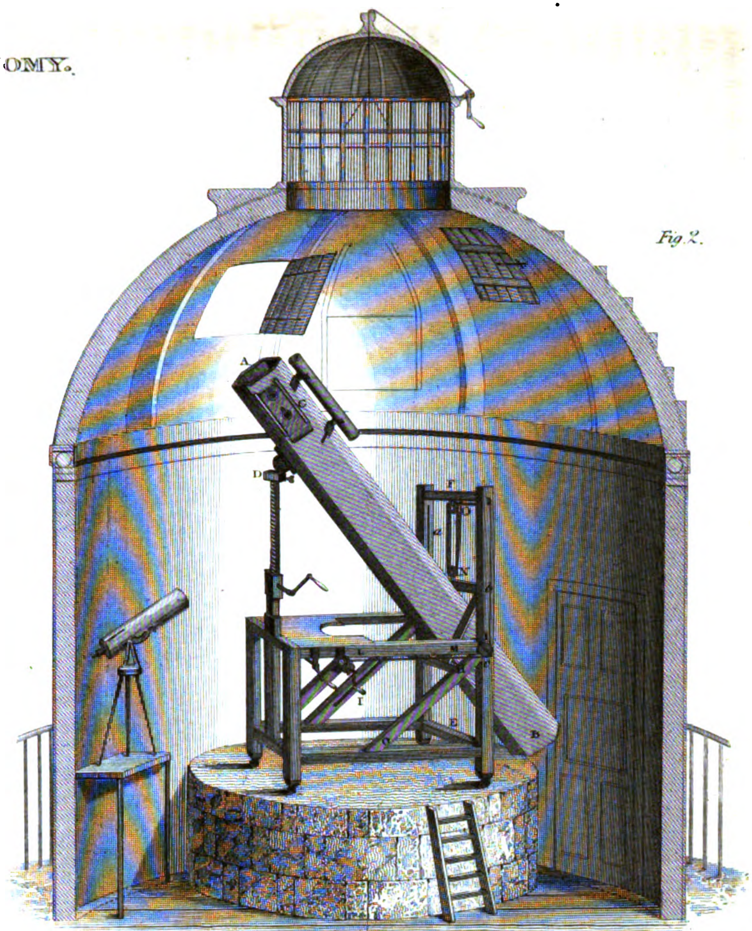


London Published by William Orr, Paternoster Row, January 1 1832.

from an idea that the weight would be too much for the pivots alone to bear. One of the supports is seen at D D, which is a kind of frame attached to the perpendicular pillars C C next to the eye; the extreme end of the axis *a*, which is not perforated, bears on a Y formed in the middle of the cross bar of this frame, which bar has an adjustable motion up and down, by means of the screw *p*, with a head divided into 50 parts, each of which parts corresponds to $\frac{3}{100}$ of an inch. Another support, every way similar to D D, is attached to the two upright pillars C C, behind the circle, which therefore cannot be seen, but it requires no farther description. The third and fourth supports of the axis are a fifth pillar, the top of which is seen through the arch of the frame D D, and its bottom near G, and a sixth pillar, P, opposite to the former. These two pillars placed nearer the middle of the stage A than the four corner pillars, C C C C, are each three feet and three inches high, and eleven inches distant from each other, measured from the interior sides we presume; they are made steady at their inferior ends, each by two cross bracing pieces, *t t*, fastened to the long pillars, C C and C C, respectively; one of which pieces, *t*, only can be seen attached to the right-hand supporting pillar, owing to the position of the figure. On the top of pillar P, may be seen a small frame, carrying a pair of friction rollers; which frame can be lowered or raised by a rod passing through the pillar down to below the stage A, under which is hidden from sight a screw of adjustment for the height of the said rod and frame of friction rollers. The rollers are placed edge to edge in the same plane, forming a kind of curved V between them, on which the projecting ring of the conical axis is supported. The situation of this ring piece, attached to the cone, is at the mean point, between the centre of the circle and the back steel pivot, which pivot is not seen in the figure. Thus one-half, or any smaller part of the weight of the circle may be made to bear on this support, by adjusting the screw of the long rod within the pillar, the nut of which we have said is under the stage A. Another support, with a frame of two friction rollers, exactly similar to the one described, is placed over the corresponding pillar, and under a corresponding annular piece embracing the second cone of the axis at its middle point; but the rod of this pillar, which adjusts the height and quantum of bearing of this second frame, does not descend so low as the stage A, but terminates a little below the middle of this pillar, which is cut into two, and joined again by a small frame of four little pillars near I, so that a hand may be put into the vacant space of the small frame, to adjust by a tapped nut acting here, instead of being put under the stage A; the reason of which is not quite evident from the appearance of the figure, nor is it explained in the original account. The end of the axis which is turned from view is perforated, and admits a lens that receives the light of a small lantern, H, placed in a line with it, and transmits this light, without the entrance of smoke or dust, to a diagonal mirror, which possesses a central hole in it, placed at the point of intersection of the telescope's line of sight, and of the central line of the axis: this mirror again reflects the received light towards the eye-piece of the telescope, and renders the two adjustable hairs, which cross one another at right angles in the united focus of the eye-glasses, distinctly visible to the eye of an observer on the darkest night.

It was found, however, that when much light was admitted into the telescope, the stars of small magnitude became invisible; on which account a contrivance was introduced for proportioning the quantity of light, according to circumstances. This contrivance consists of a parallelopiped composed of three pieces of glass, the middle one white, and the two extreme ones green, contained in a frame which has an adjustable motion by means of pulleys, two of which may be seen on the inside of the back pillars, C C, which pulleys assist the adjustment during the time of making an observation, if necessary, and limit the quantity of light, agreeably to the ascent and descent of the parallelopiped interposed between the lantern and the end of the axis. The reason of the green glasses being at both sides of the white glass, is, that the refraction of the light may be corrected by the second green glass, so as to prevent the wires in the focus of the eye-piece from appearing double. In this telescope there are six eye-pieces, five direct, and one diagonal, or what Piazzi calls prismatic, because the piece of glass that is placed at the elbow of a bent tube, put on as an eye-piece, is a prism bounded by one curved side and two rectilinear ones, the latter two of which are placed at an angle of 45°, with respect to each other; the curved side being that which first received the rays of light, and the diagonal ones being silvered. The peculiarity of this prismatic eye-piece is, that it inverts the object without reversing it; that is, the position is changed with respect to top and bottom, but not with respect to right and left. The prismatic eye-piece has two powers; one making the magnifying property of the telescope 75, and the other 130. The powers with the five direct eye-pieces are respectively 50, 75, 100, 130, and 170. The principal use of the prismatic powers is to search for stars and measure altitudes of bodies placed near the zenith; the above eye-piece with its additional tube being horizontal when the telescope is in a vertical position.

The vertical circle is graduated into 360° and figured into 90° four times over; each separate degree is also figured with Arabic numerals, and the subdivisions dotted or painted like the azimuth circle. The observed angle is read off by two different microscopes with micrometers, placed above and below the vertical circle, at the distance from each other of a semi-circle; the frame E of the superior microscope is attached to the nearest pillars, C C, as shown in the figure, just under the upper stage B, which frame contains sliding-pieces of adjustment for setting the microscope in the required position with respect to the divisions on the limb of the circle; the adjustments both of the microscope when placed, and also of its contained micrometer, are similar to those of the micrometer placed over the azimuth circle already described. The inferior microscope, F I, of the vertical circle is in every respect similar to the superior one, the micrometer's divided nut in both being placed to the right. The micrometers of these microscopes, however, have each two horizontal adjustments of motion, one parallel to the plane of the vertical circle, and the other perpendicular to that plane, and also each a vertical adjustment.

Besides these microscopes for reading off the subdivisions, each frame contains a smaller one, which we will call the secondary microscopes, the use of which is for viewing a fine plumb-line, suspended by a small screw over the superior frame E, and passing

down to G through a wooden square pipe, where the plumb may be seen immersed in the small vessel, G, full of water, above a small stage, in order to keep the line from oscillating. This vessel G may be raised or lowered by the screw that supports it. The secondary microscopes have each the same adjustments as the above-mentioned microscopes; and the plumb-line has also its point of suspension so adjustable, that it can be brought into the foci of the upper and lower eye-pieces so as to bisect the fields of view, when the microscopes are both properly adjusted.

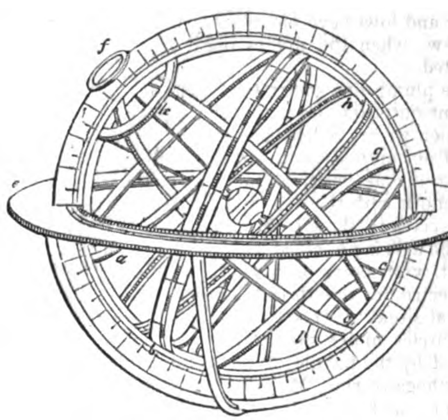
The plumb-line serves two separate, and very important purposes; for its peculiar application to both of which we are indebted to the ingenious Ramsden: first it not only serves to set the vertical axis perpendicular in one position, but by being carried round in azimuth with the axis and all the other appendages, serves to show if the perpendicular direction of the said axis is preserved with respect to all the points of east, west, north, and south; and if any deviation is detected by the thread being at one side of the original situation, then one of the adjustments of the iron circles under the inferior pivot of the axis, as effected by the handle of the compound-joint under the mahogany ring, M, must be made to verify the position; and, secondly, the horizontal axis of the vertical circle is made perfectly level by the same plumb-line; this is effected by an additional apparatus, in a very ingenious, as well as very accurate manner, which may be thus explained without a figure: suppose a bar of metal to be made of such length as, when used as a horizontal measure, would just reach from the divided face of the vertical circle to a point directly opposite it in one of the pillars at the upper end; and suppose again, this measuring bar to be applied below to a point at the lower part of the said pillar, to try if in this situation it will also touch the graduated face of the same circle; then, if the distance is found to be precisely the same in both cases, the conclusion would be from such a rough measure, that the pillar and the plane of the vertical circle are parallel, or very nearly parallel, to each other; now, as the circle was originally made by being turned on its own pivots in a large frame, its axis is necessarily at right angles to its plane, and consequently also to the surface of the pillar. Hence, if the pillar were perfectly perpendicular, the axis, on a supposition that the measures were accurately taken, would be perfectly horizontal. But we know that a plumb-line is perpendicular whenever it is at rest, therefore any contrivance that will measure very minutely the distance from the plumb-line to the plane of the circle, both above and below, will determine whether or not the axis is horizontal; this contrivance is what we have to describe:

Conceive the said bar of measurement to terminate at one end after the manner of a two-pronged fork, and suppose one-half of a compound microscope, viz. the object, object-lens, and body of the instrument, to be carried by one prong of the fork, and the eye-glass in a separate tube, borne by the other prong; and it is easy to apprehend, that the image of any small object, whatever it may be, may by the adjustment of the object-lens be made to fall into the open space between the prongs, which image may again be rendered distinct to the eye by the focal adjustment of the eye-glass; we have now got a measuring-bar with a compound microscope carried by it, in two separate halves, so that any substance that will pass between the prongs of its forked end may be brought into the field of view, and be seen magnified by the eye-glass, used on the principle of a simple microscope: let the thread of the plumb-line be this interposed body, which indeed will cover only a small portion of the field of view; but as the plumb-line is not to be moved, except by the screw at the point of suspension, nor even touched by any external object, the microscope must necessarily be brought to it, and placed in such a manner that the thread will bisect the field of view; this is done by fitting the forked end of the measuring-bar into the upper frame E, first, in such a way that it may be made to slide in and out any number of times to the same situation; then the adjustments of the frame, or of the cock of suspension, will bring the thread into the field of view; let now the object be a round dot on a slip of ivory, or mother-of-pearl would be better, perhaps, and its image may be so adjusted that the plumb-line will bisect it in its magnified state. This ingenious contrivance of producing an image in the open air has been denominated Ramsden's ghost by succeeding instrument makers, from the name of its inventor. Let now the measuring-bar, which we will suppose to be too short, be laid and supported horizontally in a direction just perpendicular to the plane of the circle, and let there be a thick pin screwed into its end next the circle, which by being unscrewed will approach the plane of the circle till it just touches it as the circle revolves, then the distance from the extreme end of this pin to the plumb-line is exactly gauged; it is of no importance what may be the total length of this gauge, provided it be kept unaltered; remove, in the next place, the measuring-rod and its apparatus at each end in statu quo, to a similar fitting made for it in the inferior frame I F; and if, when the plumb-line bisects the image of the dot here as it did before, which the adjustments of the frame only must now effect, the pin at the opposite end turns out to touch the plane of the circle below at the same right angle that it did above, then the plane is perpendicular, and the axis necessarily horizontal; but if there is any deviation, the adjusting-screw, p, on the bearing frame, D D, must rectify one-half of this deviation, and the pin which screws into the measuring-bar the other half; after a few trials above and below, the horizontal position may be given to the axis in question to the exactitude of a single second; for we have said, that a microscope may be depended on to that degree of accuracy in reading off the micrometer's scale. When the vertical circle is truly fixed, a second measuring-bar may be added at the lower frame, while the first remains at the upper one, and the turning the circle round on its axis would show both above and below when any alteration takes place in the true position, from whatever cause. But instead of using the plane of the circle itself, Ramsden judged it better to fix a little bridge, $x\,y$, over the object-glass of the telescope, with a prominence, h, which he made to come in contact with the pins of the measuring-rod above and below successively, by which means the contact is more nicely observed, and the method equally accurate. Whenever the line of collimation of the telescope is thus adjusted, it will be certain to describe a semi-circle in the heavens, when turned half round, which will be truly perpendicular to the horizon, whether that semi-circle be in the meridian or in

any given azimuth. Whenever Piazzi rectified the superior and inferior micrometers and plumb-line, he took care to use the zeros of the vertical circle as the points that bisected the circle best into two equal semi-circles; and he gave as a reason, that he found these did not deviate more than a quarter of a second from their true places. When the vertical circle is used in taking altitudes, it may be clamped by a piece, *k*, on the pillar P, which when loose will allow a quick motion, but when fast will only permit a very slow one by means of the handle, V, of the compound-joint, which like that at Q is connected with the tangent-screw out of sight. These, we believe, are all the essential parts of this highly-important instrument.

The theory of the telescope would not be understood by the reader without a preparatory acquaintance with the science of optics, and we purpose under the article TELESCOPE giving a very full account of that form of the instrument which is best fitted for astronomical purposes; but there is a very important part of the furniture of the observatory which must be noticed here, we mean the frame-work and supports for the telescope. One of these, contrived by Sir William Herschel, is represented in the centre of the observatory (Plate, ASTRONOMY, *fig.* 2), in which A is the elevated mouth of a seven-feet tube, and B the place of the large speculum that reflects the rays of light back to the small diagonal plane metal near C, which, by a second reflection, brings them to a focus at the eye-piece below C, as seen in the engraving. Above C is the finder, the upper end of which has a small achromatic object-glass, and the lower end the eye-glass. The upper end of the tube rests on a support, D, which is capable of being raised or depressed by a pinion on the axis of the handle under D, while the lower end rests on the horizontal bar of the frame E F, which is suspended by a pulley over F; the four pivots *a*, *b*, *c*, and *d*, of the said frame, sliding in the open grooves, seen near those letters in the main frame, keep the small frame in any given situation, and allow a free motion, first down the vertical, and then down the inclined pieces that compose the main frame, as low as to G and H; and when the lower end of the tube has been depressed into this situation, the tube may have an elevation approaching towards the zenith: for not only is the upper end elevated by the handles at J for the quick, and at D for the slow motions; but the lower one is depressed by the handle at I, round which the cord is coiled, that goes round a fixed roller at K, and two others at L and M, before it embraces the pulley N, and is hooked to a pin at O above the frame. The rest of the main frame is so clearly exhibited in the engraving, that no farther description of it is necessary. In some of the instruments of this construction, when the handle J is omitted, and a quicker motion in altitude is required, and also a greater elevation than can be given simply by the handle at D, the second square stem that carries the pinion of the handle, is raised by hand, and kept to its elevation by means of a second rack, when this squared stem is lowered again. The quick motion in azimuth is given by sliding the lower end of the tube gently along the bar on which it rests, or by moving the whole frame, which moves on castors; but the slow motion is produced by a screw. It is scarcely necessary to add that the eye of the observer is applied to the side of the tube near its mouth, when the finder has pointed the tube properly to its object.

Most observatories possess an instrument called an armillary sphere. In the present day, it is more used for elucidating the general principles of astronomy, than for practical research; it may, however, be advisable to give a description and graphic delineation of the instrument.



It consists, as is seen in the figure, of an artificial sphere, composed of a number of circles of metal, put together so as to represent the ecliptic zodiac, tropics, and other imaginary circles in the heavens, in their natural order.

The earth is situated in the centre of this sphere, in the same plane with the rational horizon, which horizon, *d*, is generally represented by a broad silvered circle, divided into degrees, &c. The whole machinery is usually supported upon a brass stand, and is moveable about an axis, within a brass meridian like the common globes.

This meridian is likewise moveable within the silvered horizon, so as to admit the elevation or depression of the poles, *f*. The use of this sphere is to assist the imagination in conceiving the apparent motion of the celestial bodies. The student must suppose himself to be placed upon the earth, with the various circles in the heavens revolving round him from east to west.

Having in the preceding pages entered pretty fully into the construction of the instruments employed in practical astronomy, it may now be necessary to furnish a notion of the sort of edifice best fitted for containing them. A very useful observatory is represented in Plate, ASTRONOMY, *fig.* 2. It consists of a circular building with a moveable roof of similar form. The latter is made to revolve on friction rollers, and a contrivance of a winch and pulley enables the observer to elevate or depress the moveable ceiling in the lantern at pleasure. Various instruments are seen round the room, and amongst the rest an armillary sphere, to which allusion has already been made. Shutters for presenting the tube of the telescope in various aspects are also employed, towards one of which the large instrument is directed.

We do not purpose in the present place entering into the history of observatories, as that branch of the subject will be discussed under the article itself; but it may be advisable to give a description of a very excellent modern establishment in the sister

kingdom, erected without reference to expense for the express purpose of practical astronomy.

The observatory belonging to Trinity College, Dublin, commonly called the Dublin Observatory, was begun in the year 1783. It was founded by Dr. Francis Andrews, provost of that college, who bequeathed a large income for this purpose, which was to commence upon a particular contingency happening in his family. When this event had taken place, the College, with their wonted zeal for the promotion of science, determined not to lose time by waiting for the accumulation; but advanced from their own funds a sum considerably exceeding the amount of the original bequest.

They chose for their professor of astronomy and observer, the Rev. Dr. Usher, a man of extensive learning and indefatigable research, who was directed to proceed to England, to order from Mr. Ramsden the best instruments he could make, without any limitation of expense.

The apparatus first ordered was a transit instrument of six-feet focal length, with a four-feet axis, bearing four inches and a quarter aperture, with three different magnifying powers up to 600. An entire circle of ten-feet diameter, on a horizontal axis for measuring meridian altitudes; an equatorial instrument, with circles of five feet in diameter: an achromotic telescope, mounted on a polar axis, and carried by an heliostatic movement. Regulators were also ordered from Mr. Arnold, without any limitation of price. The situation chosen for the observatory is on elevated ground, about four miles from Dublin. The foundation is a solid rock of limestone, of several miles extent; and the soil is very favourable, being a calcareous substance, called limestone gravel, which is remarkable, absorbs rain, and thus contributes to dry the atmosphere.

The plan of the building unites at once both elegance and convenience: it fronts the east, and the lower range of windows and doors are twenty-three in number. In the centre there is a magnificent dome of three stories high, with a moveable roof for the equatorial instrument, which is placed upon a pillar of sixteen feet square, of the most substantial masonry, and surrounded by a circular wall of a foot distance, that supports the moveable dome, and also the floors, which in no part touch the pillar; thus, no motion of the floor or wall can be communicated to the instrument. The aperture for observation in the dome is two feet and a half wide.

But the most important erection belonging to this establishment is behind the main building, and at right angles to it, in order to obtain an uninterrupted view both north and south. This is the meridian or transit room, which contains both the transit instrument and the circle. It is thirty-seven feet long, twenty broad, and twenty-one high. Fine pillars of Portland stone are erected for both instruments, and the floor is so framed as to let all the pillars rise totally detached from it: and such was Dr. Usher's attention to extreme accuracy, that he first ascertained the pillars to be perfectly homogeneous, lest any variety in their substance might admit of a difference in their expansion or contraction by heat, cold, or other changes of atmosphere.

We cannot conclude this view of practical astronomy without quoting a remark made by a very enlightened critic in the *Quarterly Review*, who says, "when we look at the state of science on the Continent, pursued by academicians freed from the embarrassments of professional labour, and when we look at their numerous and well-appointed observatories, we shrink from the comparison which is thus forced upon our attention. We feel as if it were a species of treason to record the fact, that within the wide range of the British islands there is only one observatory, and scarcely one supported by the government! We say scarcely one, because we believe that some of the instruments in the observatory at Greenwich were purchased out of the private funds of the Royal Society of London. The observatories of Oxford, Cambridge, Dublin, Edinburgh, Armagh, and Glasgow, are all private establishments, to the support of which government contributes nothing." The consequence of this is, that many of them are in a state of comparative inactivity, and of but little service to the scientific world.

Works of reference on astronomy have not multiplied to the same extent as the printed treatises on many other sciences. The labour of a long life is necessary to the formation of a good book; and till the formation of Mr. Babbage's modes of calculation, a series of tables would alone occupy years of mathematical labour.

Of the numerous works on astronomy, we shall only mention here the latest and most important manuals and elementary works: *Astronomie par de Lalande*, 3rd edit., Paris, 1792, 3 vols., 4to. (there is an abridgment of it—*Abrége d'Astronomie par de Lalande*, Paris, 1795); *Astronomie Theorique et Pratique, par Delambre*, Paris, 1814, 3 vols., 4to.—a work important for professional astronomers; *Schubert's Theoretical Astronomy*, Petersburgh, 1798, 3 vols., 4to., and the new French edition of the same work, 1822; *Biot's Traité Elémentaire d'Astronomie Physique*, 2nd edit, Paris., 1810, 3 vols.; *Laplace's Exposition du Système du Monde*, 5th edit., Paris, 1824 (a general exposition of the results developed in the large work, *Mécanique Céleste*); *Bode's Illustrations of Astronomy* (which is confined to the less difficult propositions of geometry and astronomy), 3rd edit., Berlin, 1808, 2 vols.: together with this work, we may mention *Burjas' Manual of Astronomy*, Berlin, 1794, 5 vols., which requires, however, more extensive knowledge. Excellent, though very condensed, is *Bohnenberger's Astronomy*, Tübingen, 1811. *Piazzi's* Italian *Manual of Astronomy* is a good work. Among the English treatises are *Woodhouse's Elementary Treatise on Astronomy*, 1823, and *Ferguson's Lectures on Astronomy*, a popular work; also *Vince's Complete System of Astronomy*, 3 vols., 4to., with additions, 1814. To astronomers, practical and theoretical, *Bessel's Observations at the Observatory of Königsberg*, which have appeared in folio since 1813, are indispensable. Notices of astronomical tables may be found in the larger astronomical treatises mentioned. With respect to astronomical periodicals, *Zach's Monatl. Correspondenz zur Beförderung der Erd- und Himmels- Kunde*, with which is connected *Lindenau's and Bohnenberger's Astronom. Zeitschr.*, is continued under the title *Correspondence Astronomique, Géographique*, &c. *du baron de Zach*. Schumacher has also published, in Copenhagen, since 1822, *Astronomische Nachrichten*. The latest observations may be also found in the Paris *Connaissance des Tems*, and in the Berlin *Astronomisches Jahrbuch*, which has been published for more than fifty years. The history of astronomy may be found at large in Montucla's

Histoire des Mathématiques, 4 vols., 4to.; in Delambre's *Histoire de l'Astronomie Ancienne, celle du Moyen Age et Moderne*, Paris, 1817, 5 vols., 4to.; and in *Bailly's Histoire de l'Astronomie*, of which the first volume appeared in 1771, containing the history of ancient astronomy, and the three other volumes, 1779 and 1782, containing the history of modern astronomy, followed, in 1787, by his *Traité de l'Astronomie Indienne*, which latter work, however, must be used with precaution, on account of the inclination of the author to adopt theories on insufficient grounds, which indeed is one of the faults of his school.

Mrs. Somerville's excellent and learned treatise on the *Mechanism of the Heavens*, lately published, deserves the highest praise, both for general research and high mathematical attainments. This work will alone give a character to the literature of the age in which we live, and tend to place our fair country-woman foremost in the ranks of astronomical science.

Astroscope, an astronomical instrument, composed of two cones, on whose surface the constellations are delineated, by means of which the situation of the stars may easily be known.

Astroscopia; the art of examining the stars by telescopes, or, in plainer terms, practical astronomy.

Astrothemata, in *Astrology*, the positions of the stars in a plan of the heavens.

Astrothesia; the same as Astrum, which see.

Astrum; a constellation or assemblage of stars.

Astrum, in *Alchemy*, a term employed to denote the power imparted by chemical mixture.

Asymptote; commonly, a straight line, which approaches a curve line, so that the distance between them is constantly diminishing, although they can never meet, even if indefinitely continued. Hence Leibnitz called infinite spirits the *asymptotes of the Deity*. An asymptote may also be a curve.

Atabal; a kind of tabor used among the Moors, which is probably a word of Moorish extraction.

Atabulus; a provincial wind much felt in Apulia, of a dry and noxious quality. The ancient naturalists speak of the atabulus in terms of horror, on account of the ravages it made among the fruits.

Ataxy signifies irregularity of crisis, and paroxysms of fevers.

Ataraxia; exemption from disease or vexation. "The sceptics," says Glanville, "affected an indifferent equiponderous neutrality, as the only means to their ataraxia and freedom from passionate disturbances." So much for the clearness and simplicity of a much-praised author.

Atche, in *Commerce*; the smallest silver coin current in Turkey, worth about one-third of a penny sterling.

Atchievement, in *Heraldry*, denotes the arms of a person or family, together with all the exterior ornaments of the shield, as helmet, mantle, crest, scrolls, and motto, together with such quarterings as may have been acquired by alliances, all marshalled in order. *Hatchment*, as a funeral memento, is a vulgarism of the above.

Atebras, in *Chemistry*; a subliming vessel.

Ategar; a weapon among the Saxons, which seems to have been used as a hand dart.

A Tempo, in *music*; of similar signification with *a battuta*, and, like that expression, seldom used but when the time has been interrupted. *A tempo*, in any kind of fencing or fighting, means a blow or thrust at the same time with the antagonist's blow or thrust. It is, of course necessary that *a tempo* blows should be made in such a way as to afford at the same time a guard against the other's thrust, or to prevent its full effect. This kind of blow takes place particularly in fighting with the broad-sword, when the antagonist leaves himself much exposed.

Atempo Giusto, in *Music*, signifies, to sing or play in proper time.

Athanasia, in ancient *Medicine*; an epithet given to a kind of antidotes, supposed to have the power of prolonging life, even to immortality. In the *Augustan Dispensatory* we still find a medicine under the appellation of "athanasia magna," recommended against dysenteries and hæmorrhages.

Athanati; a peculiar body of cavalry, among the ancient Persians, consisting of 10,000 men, always complete, because, when any one of them died another was immediately put into his place.

Athanor, in *Chemistry*; a digesting furnace, which retained the heat for a long period of time, and was so contrived that it might be increased or diminished at pleasure.

Athena, in *Medicine*; a plaster or liniment recommended against wounds of the head and nerves, of which we find descriptions given by Oribasius, Ælius, and Æginata.

Athenatorium, in *Chemistry*; a thick glass cover, to be luted to a cucurbit when the alembic is taken off.

Athenorius Catapotium, in *Medicine*; a cough pill mentioned by Celsus, consisting of myrrh, pepper, castor, and opium.

Athenippum, in *Medicine*; an affusion for the eyes.

Atheroma, in *Surgery*, is a soft, pultaceous, uninflamed tumor; generally contained within a cyst, or bag. The cure of this swelling consists in its removal with a scalpel. It is very common on the finger joints.

Athwart, when used in navigation, implies across the line of the course.

Athwart-Hawse; the situation of a ship when she is driven by the wind, tide, or other accident, across the fore-part of another. This phrase is equally applied when the ships bear against each other, or when they are at a small distance: the transverse position of the former to the latter being principally understood. *Athwart the fore-foot* denotes the flight of a cannon-ball from one ship across the course of another, to intercept the latter, and oblige her to shorten sail, that the former may come near enough to examine her.

Atlantides, in *Astronomy*; another name for the Pleiades.

Atlantides, in *Architecture*; pillars used like the Caryatides, to support an edifice.

Atlas, in *Anatomy*; the first vertebræ of the neck, which supports the head.

Atlas, in *Commerce*; a very beautiful species of Chinese manufacture, now but little used. It consisted of a mixture of metal and silk, and was bought with avidity at very high prices.

Atmosphere. This is the ordinary title of the elastic fluid in which we live and breathe. The weight and pressure of the atmosphere has already been examined under the article Air, and will be further discussed when treating of the Barometer; but there are some interesting facts connected with the atmosphere which may properly have a place here.

The atmosphere may be considered a universal solvent, and though itself *inodorous*, it is the medium of all smells, and dissolving the different odorous effluvia, is charged with the emanations of all the various substances it sweeps.

When we reflect upon this ever-agitated heterogeneous fluid, compounded of the most active elements of life and destruction, constantly combining,—separating, now evident to the most ordinary sense, now escaping the grasp of imagination, we cannot, rationally, be surprised at the little, comparatively, that is really known concerning it. All within the power of the most ardent student is to collect the few facts that are established, to dismiss conjecture and hypothesis, and to apply himself to make additions to our knowledge by carefully observing, and accurately and luminously describing, the processes during which he is permitted to be present.

"By invisible, but ever-active agencies, the waters of the deep are raised into the air, whence their distribution follows, as it were by measure and weight, in proportion to the beneficial effects which they are calculated to produce. By gradual, but almost insensible, expansions the equipoised currents of the atmosphere are disturbed, the stormy winds arise, and the waves of the sea are lifted up; and that stagnation of air and water is prevented which would be fatal to animal existence. But the force which operates is calculated and proportioned; the very agent which causes the disturbance bears with it its own check, and the storm, as it vents its force, is itself setting the bounds of its own fury."—*Daniel's Essays.*

It is evident, from a slight view of these "complicated and beautiful contrivances," that it is hopeless to expect that all the causes of the phenomena of the atmosphere will ever be entirely attained by human science. At present but few are known, and those imperfectly. Amongst the principal ones which most affect the subject of our present inquiry are, undoubtedly, heat and electricity. The first raises and suspends the evaporated waters invisibly in the air, until some more powerful attraction dissolves the union, and the deserted moisture, exposed to view, falls again to the earth, and revisits it in the various forms of clouds, mist, rain, dew, snow, hail, sleet, and hoar-frost. To electricity may be principally attributed the more splendid phenomena of lightning, the aurora-borealis, and the other igneous meteors. And the effect of these causes, variously combined and infinitely modified by other agents, is felt in those currents of atmospheric air, which are described by a sacred writer, as "going toward the north, and toward the south, as whirling about continually and returning again according to their circuits."

Professor Leslie furnishes the following plain and simple facts on the subject.

"The mean height of the barometer (that is, the mean weight or pressure of the atmosphere) at the level of the sea, is the same in every part of the globe.

"The barometer constantly descends in a geometrical progression for equal ascents in the atmosphere, subject to a correction for the decreasing temperature of the elevation.

"The mean temperature of the earth's surface increases gradually from the poles to the equator.

"The mean temperature of the atmosphere decreases from below upwards in a regular gradation.

"The barometer at the level of the sea is but slightly affected by the annual or diurnal fluctuations of temperature; but, in the higher regions of the atmosphere, is, on the contrary, greatly affected by them.

"The heating and cooling of the atmosphere, by the changes of day and night, take place equally throughout its mass.

"The average quantity of vapour in the atmosphere decreases from below upwards, and from the equator to the poles.

"The western coasts of the extra-tropical climates have a much higher mean temperature than the eastern coasts.

"A wind generally sets from the sea to the land during the day, and from the land to the sea during the night, especially in hot climates.

"Between the tropics the fluctuations of the barometer do not much exceed one quarter of an inch, while, beyond this space, they reach to three inches.

"In the temperate climates the rains and the winds are variable.

"As we advance towards the polar regions, we find the irregularities of the wind increased; and storms and calms repeatedly alternate, without warning or progression.

"In the extra-tropical climates, a fall in the barometer almost always precedes a period of rain, and indicates a change or acceleration of the aerial currents.

"Barometers, situated at great distances from each other, often rise and fall together with great regularity.

"More than two currents may often be traced in the atmosphere at one time, by the motions of clouds, &c.

"The force of the winds does not always decrease as the elevation increases; but, on the contrary, is often found to augment rapidly.

"The variations of the barometer are less in high situations than in those at the level of the sea.

"In Great Britain, upon an average of ten years, westerly winds exceed the easterly in the proportion of 225 to 140; and the northerly winds exceed the southerly, as 192 to 173.

"Northerly winds almost invariably raise the barometer, while southerly winds as constantly depress it.

"The most permanent rains from this climate come from the southern regions.

"The mean height of the barometer varies but little with the changes of the seasons.

"The apparent permanency and stationary aspect of a cloud is often an optical deception, arising from the solution of moisture on one side, and its precipitation on the other.

"The quantity of vapour in the atmosphere in the different seasons of the year (measured on the surface of the earth, and near the level of the sea) follows the progress of the mean temperature.

"The pressure of the aqueous atmosphere, separated from that of the aerial, generally exhibits directly opposite changes to the latter.

"Great falls of the barometer are generally accompanied by a temperature above the mean for the season, and great rises by one below the same."

The same authority also states, that "the British islands are situated in such a manner as to be subject to all the circumstances which can possibly be supposed to render a climate irregular and variable. Placed nearly in the centre of the temperate zone, where the range of temperature is very great, their atmosphere is subject, on the one side, to the impressions of the largest continent of the world; and, on

the other, to those of the vast Atlantic Ocean. Upon their coasts the great stream of aqueous vapour, perpetually arising from the western waters, first receives the influence of the land, whence emanate those condensations and expansions which deflect and reverse the grand system of equipoised currents. They are, also, within the frigorific effects of the immense barriers and fields of ice, which, when the shifting position of the sun advances the tropical climate towards the northern pole counteract its energy, and present a condensing surface of enormous extent to the increasing elasticity of the aqueous atmosphere.

Heat is one of the most important agents resorted to in the economy of creation for revivifying the atmosphere. This is effected by the constant operation of aerial currents familiarly termed *winds*. By this means the whole of the ingredients of the atmosphere are continually amalgamated together; for we find that though the atmosphere may diminish in lightness as we ascend, there is precisely the same general character pervading its particles. Without winds the air would become putrescent and stagnant by the thousand effluvias of a crowded city, and our own, "giant metropolis," would be little better than one vast lazar house. It should, however, be borne in mind, that the smoke of our coal fires is not as injurious to health as is generally imagined, and the prejudice which originated in Evelyn's "Fumifugium," is now giving way to a more accurate chemical acquaintance with the antiseptic properties of common carbon. To explain the theory of the winds, we cannot do better than select one particular species of aerial current, which may serve to illustrate the phenomena generally.

The *trade-winds*, which, within the tropics at all times constantly blow from the east, but somewhat vary their force, and decline a little to the north or the south, according to the latitude and the season, are the most remarkable of all the aerial currents, and of signal importance in navigation. These steady breezes favoured the voyages of Columbus, and conducted him to the discovery of the Mexican archipelago. The same powerful stream afterwards drew the Portuguese from their southern course, and carried them to the shores of the Brazils. Since the character and extent of those winds have become perfectly known, the navigator reckons safely on their aid, and shapes his voyage in such a way as to reduce its performance almost to a calculation.

The cause of the trade-winds, however, is not obvious, or very easily traced. Various attempts have been made to explain their principle of action, yet seldom on any solid or accurate principles. It would form an interesting discussion to examine the different hypotheses advanced; but we can afford room to notice very briefly the most considerable only of these opinions.

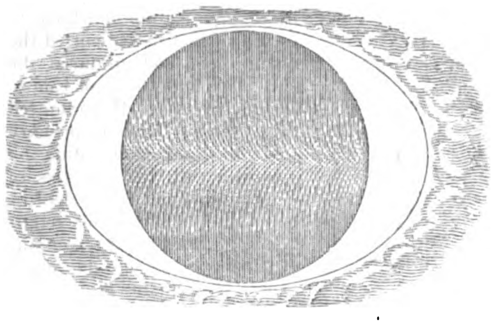
Des Cartes, and his followers, imputed the trade-winds to the inertia of the atmosphere, which they conceived prevented the air acquiring the full rotation of the earth, especially near the equator. The wind being thus left behind, as the globe rolled from the west, would have an apparent motion in the contrary direction, and seem to blow from the east. But it may be urged, that as passengers almost insensibly gain the celerity of the ship which carries them, so every portion of the incumbent atmosphere, though more loosely attached to the terraqueous surface, must soon acquire the peculiar motion corresponding to the parallel of latitude. Nor would the inequality of such combined movements in the air at all disturb the order and arrangement of its general mass.

Dr. Halley gave a different explication of the origin of trade-winds, which seems very plausible, and was for some time deemed quite satisfactory. This able philosopher and experienced navigator supposed that the spot where the sun's vertical rays exert their utmost heating energy, being in the lapse of a day successively transferred from east to west round the circumference of the globe, must, as a centre of confluence, draw in its train a current of air. The current thus formed would result from the excess of the air streaming from the east above that from the west; and it would therefore advance with a tardy pace, following at a distance the powerful energy of the sun. The same easterly wind might incline towards the north or the south, according as the great luminary appears to approach the northern or the southern tropic.

But it should be observed, that the torrid zone stretches mostly over the ocean, and includes only a narrow portion of land. The heat excited in succession through that liquid tract, by the diurnal passage of the sun, is hence extremely small, and hardly sufficient to produce the gentlest air. Nor could even this feeble current have a decided and constant direction: it would only tend towards the heated part of the surface of the ocean. In the morning, it would breathe from the west; about noon, it would become neutral, and die away; and in the evening, it would again spring up and flow from the east. Near midnight this current would sink into a perfect calm. The hypothesis will, therefore, not bear any strict examination. It is neither adequate to the production of such effects, nor accordant with the actual phenomena of the trade-winds.

The first who succeeded in taking a correct view of the question was George Hadley, in a short paper inserted in the *Philosophical Transactions* for 1735. By combining in some measure the idea of Des Cartes with the opinion of Halley, he produced a clear and simple account of the cause of trade-winds, which appears entirely consistent and free from every objection. Though the daily variation of temperature be very inconsiderable within the tropics, yet the annual accumulation of heat renders the equatorial regions much warmer than the higher latitudes, and consequently maintains a perpetual current of air from either side. If those aerial motions were not modified by the figure and rotation of the globe, there would always be two opposite winds blowing directly from the north and from the south to the equator. But the stream which perhaps originates at the northern tropic, in advancing to the equator, must seem gradually to deflect towards the west, in consequence of the increasing velocity with which the successive parallels of latitude are carried eastwards. During the time this current takes to perform its journey, it is apparently transported to the west, through a space equal to the excess of the arc traced by the tropic. The current from the southern tropic is equally bent towards the west. When both of them meet at the equator their opposite impulsions from the north and south are extinguished, and they flow directly west in a single united stream, and with accumulated force. The apparent motions of the different streamlets, which from both hemispheres

conspire to constitute the trade-wind, is represented in the accompanying diagram.



But it is not enough to connect the general facts; a complete theory should harmonize all the subordinate details. An easy calculation accordingly conducted to those precise results which are commensurate and exactly congruous with the actual phenomena. The trade-wind may be reckoned to begin about the latitude of 25 degrees. At this parallel, the mean temperature is four centesimal degrees colder than immediately under the equator, which difference of heat may graduate through the atmosphere to the altitude of 10,000 feet. Wherefore, the expansion of the air at the equator, which draws to it a meridianal wind, will amount to a column of 100 feet. The velocity of the current hence produced, must be about 80 feet every second, which corresponds to 54 miles in the hour. But each point on the parallel of 24°, is carried eastward by its revolution about the earth's axis, 7 miles faster every hour than on the parallel of 25°. Consequently, when the wind arrives at the parallel of 24°, it will seem to have acquired a tendency of 7 miles an hour to the west. As it reaches the successive parallels of 23°, 22°, 21°, &c. it will gain continual, though decreasing additions to its apparent westerly course, which at the equator will have augmented to 104 miles in the hour.

In this calculation, we have made no deduction for the resistance which the streams of air must experience in sweeping over the surface of the globe, because no experiments have been made to ascertain the effect of such retardation. It is no doubt less on the ocean than on the land, and must evidently be diminished in proportion to the depth of the mass of fluid which is borne along. Still, however, this obstruction, joined to this impediment of internal motion, must be very considerable; and we may safely reduce the numbers before stated to one-third, which would give 18 miles an hour for the celerity of the primary meridianal wind, and 35 miles for that of the oriental or trade-wind, resulting from the influence of the figure and rotation of the earth.

From the laws of universal attraction it has been inferred, that these celestial bodies must act upon the atmosphere, or that they must occasion a flux and reflux of the atmosphere, as well as that of the ocean. Hence it has been alleged, that though we cannot discover aerial tides, of ebb or flow, by means of the barometer, because columns of air of unequal height, but different density, may have the same pressure or weight; yet the protuberance in the atmosphere, which is continually following the moon, must, they say, of course produce a motion in all parts, and so produce a wind more or less in every place, which, conspiring with, or counteracted by the winds arising from other causes, makes them greater or less. Several dissertations to this effect were published, on occasion of the subject proposed by the Academy of Sciences at Berlin, for the year 1746. Although the atmospherical air is much more variable than water, and the action of the sun and moon upon it becomes much less apparent to us, because they must frequently concur with, or be counteracted by the much more powerful effects of heat and cold, of dryness and moisture, of winds, &c., so that their action upon the barometer has been long disputed and even denied; yet that the moon in particular, as well as the sun, has such an action, has been for a considerable time surmised; and of late years it has been in a degree observed and rendered sensible by means of very accurate and long-continued barometrical observations, and perceived merely by taking a mean of the observations of many years. Toaldo, the learned astronomer of Padua, after a variety of observations made in the course of several years, found reason to assert, that, at the time of the moon's apogeum, the mercury in the barometer rises the 0.022 of an inch higher than at the perigeum; that at the time of the quadratures, the mercury stands 0.008 of an inch higher than at the time of the syzygies; and that it stands 0.022 of an inch higher when the moon in each lunation comes nearest to our zenith, (meaning the zenith of Padua, where the observations were made), than when it goes farthest from it.

In the seventh volume of the *Philosophical Magazine*, there is a paper of L. Howard, Esq. which contains several curious observations relative to this subject. This gentleman found, both from his own observatians, and from an examination of the Meteorological Journal of the Royal Society, which is published annually in the *Philosophical Transactions*, that the moon had a manifest action upon the barometer. "It appears," he says, "to me, evident, that the atmosphere is subject to a periodical change of gravity, by which the barometer, on a mean of ten years, is depressed at least one-tenth of an inch, while the moon is passing from the quarters to the full and new; and elevated, in the same proportion, during the return to the quarter." A great fall of the barometer generally takes place before high tides, especially at the time of new or full moon.

The causes, it is said, which render the diurnal tide of the atmosphere insensible to us, may be the elasticity of the air, and the interference of the much more powerful effects of heat, cold, vapours, &c,

It has been calculated by D'Alembert, from the general theory of gravitation, that the influence of the sun and moon in their daily motions is sufficient to produce a continual east wind about the equator. So that, upon the whole, we may reckon three principal daily tides, viz. two arising from the attractions of the sun and moon, and the third from the heat of the sun alone; all which sometimes combine together, and form a tide of great magnitude.

In corroboration of the opinion of the influence of the sun, and principally of the moon, in the production of the wind, we must likewise mention the observations of Bacon, Gassendi, Dampier, Halley, &c.; namely, that the periods of the year most likely to have high wind are the two equinoxes; that storms are more frequent at the time of new and full moon, especially those new and full moons which

happen about the equinoxes; that, at periods otherwise calm, a small breeze will take place at the time of high water; and that a small movement in the atmosphere is generally perceived a short time after the noon and the midnight of each day.

the mean temperature of the air.

ATOLLENS OCULI, in *Anatomy*, one of the muscles of the eye, usually called the elevator oculi.

ATOMIC PHILOSOPHY. The nature of the ultimate elements of which bodies are constituted, has been a fruitful source of speculation among philosophers of all ages. From the earliest times of antiquity down to the present day, two opinions directly opposed to each other have divided the world on this subject; the one, that matter is composed of an assemblage of minute particles or *atoms* incapable of farther division,—the other, that there is no limit to its divisibility, the smallest conceivable portion still consisting of an infinity of parts. The first of these theories, which is commonly distinguished by the name of the Atomic philosophy, was originated in Greece by Leucippus; it was supported by Democritus, and subsequently considerably improved by Epicurus. It also existed at a very early period among the Hindoos, as Mr. Colebrooke* has shown, and formed the prominent feature of the doctrines of the Vaiseshica school of philosophy. According to Canade, the reputed founder of that sect, material substances are primarily atoms, and secondarily aggregates. These atoms are eternal, and the mote which is seen in a sun-beam, and which is the most minute of perceptible things, consists of several of them. They are simple and uncomposed; else the series would be endless, and were it pursued indefinitely, there would be no difference of magnitude between a mustard-seed and a mountain, a gnat and an elephant, each alike consisting of an infinity of particles. The ultimate atom then is simple. Two of these atoms concurring by an unseen peculiar virtue, the creative will of God, time, or other competent cause, constitute a binary or double atom, which is the first compound; by the concourse of three binary atoms, a ternary atom is produced, which is the second compound; the next is formed by the union of four ternary atoms, and is a quaternary atom, and so on to grosser masses or aggregates. In this manner Canade accounts for the formation of all material bodies, from these four of the nine substances or elements recognised by the Hindoo philosophers, the existence of which is deduced from distinct perception. Thus, great earth, as he terms it, is produced from earthly atoms, great water, from aqueous atoms, great light or heat, from luminous, and great air from aerial ones.

This doctrine bears a considerable analogy to that embraced by the earlier philosophers of Greece, who in many instances seem to have entertained views more conformable to the principles of modern science than their successors. Anaxagoras supposed the material world to consist of minute particles, but contended that those particles were of different kinds, the peculiar form and properties of any substance depending on the nature of the particles of which it was chiefly composed. He also maintained the existence of an active intelligent principle, or infinite mind, distinct from matter, and possessing a power of motion within itself, the communication of which, to the passive particles of the material mass, caused the union of the homogeneous ones, and produced the various forms of nature. The hypothesis of Empedocles was a simplification of this. He admitted the existence of only four different kinds of primary particles, and accounted for their aggregation by conceiving them to be endued with the qualities of friendship and discord; or, as in modern scientific language we should call them, affinity and repulsion. These qualities being excited by the communication of motion to the original material mass, through the agency of the active intelligent principle of nature or Divine mind, their operation he supposed to lead to the union of homogenous atoms, and the separation of heterogenous ones; and consequently to the formation of four elements, as he termed them, —air, earth, fire, and water, by the intermixture of which, in various proportions, he imagined all other substances to be produced. Both of these philosophers maintained the existence of several essentially distinct kinds of particles; they disagreed only as to the number of those classes, Democritus admitting but four, and Anaxagoras imagining a separate class for every different compound in nature. Leucippus attempted to reduce it still farther; he derived the whole material world from one elementary kind of matter, consisting of minute indivisible corpuscles or *atoms*, of various shapes, insensible, and possessed of an intrinsic power of motion. By the agency of this power, the intervention of a Divine mind in the formation of the various objects in nature, which had been recognised by preceding philosophers, was dispensed with, and their production accounted for by the fortuitous concurrence of atoms of similar forms. Independently of its atheistical tendency, a fatal objection to this doctrine is, that each particular atom being supposed insensible, no collection of atoms can become sensible. It was probably, as Bayle thinks, from a conviction of this difficulty that Democritus, the follower of Leucippus supposed every atom to be endued with a soul, although on other points he, agreed with his master. But Epicurus, who is considered the great supporter of the ancient atomic philosophy, rejected this innovation, and adhered in this respect to the original notion of Leucippus. He ascribed the formation of the various material bodies of the universe to the union sometimes attending the casual collision of two wandering atoms, which, from the jagged or pointed shape of one of them, might happen to adhere. The compound would probably possess interstices just adapted to corresponding projections of other atoms which would consequently on meeting, unite to it. When these primary atoms were closely connected, with but little space between, they produced solids, such as stones and metals; when loose and disjoined, the resulting compound was of lax texture, as wood, water, and vapour.

The arguments adduced by the advocates of the doctrine of the existence of ultimate atoms, were various. They contended that without, such an arrangement, there would be no durability in the system of nature; that the component particles of matter, gradually worn down by constant attrition, during a period of indefinite extent, would eventually become

* Essay on the Philosophy of the Hindoos, part II, in the *Transactions of the Royal Asiatic Society*, vol. I, page 104; and not in the *Asiatic Researches*, to which Dr. Daubeny by mistake refers, in his *Introduction to the Atomic Theory*.

unable to form any thing possessing bulk and solidity; or else would produce substances of a very different nature from those which they gave rise to formerly, when in a less comminuted state. And hence, added they, the races of animals and the tribes of plants could not have preserved their uniformity for so long a period, if the particles out of which they were formed had undergone any change in size and figure; for, from those two qualities arose, according to their doctrine, all the distinguishing marks which characterise a body. They also argued, that as every material body which comes under our observation does possess a definite size, so ought each of the parts of which it consists.

Among the moderns, the same diversity of opinion prevailed which divided the ancient world. By Leibnitz, the existence of atoms was denied, as inconsistent with two of his leading dogmas—the law of continuity, and the doctrine of a sufficient reason. The very notion of an atom, he contends, implies that of absolute hardness; now, if two bodies perfectly hard, and therefore altogether inelastic, were to meet with equal and opposite motions, they must both necessarily stop at once. Hence, to suppose the existence of bodies so constituted as to pass instantly from a state of rapid motion to one of perfect rest, is inconsistent with the law of continuity, which implies that no change can take place abruptly, or without passing through the intermediate gradations.

More intelligible are the arguments advanced by Des Cartes, and the host of philosophers who attached themselves to his theory during the seventeenth century; these contented themselves for the most part with proving, that no body can be considered in a mathematical sense incapable of division. No compound or visible bodies, it is well known, ever come into immediate contact with each other, or influence each other by means of simple solidity. The earth is affected by the sun, the moon by the earth; the waters of the earth by the moon. The particles of all bodies deemed the most solid and impermeable, are capable of approaching nearer, or receding farther from each other, by an application of different degrees of cold or heat. We can, hence, it is said, form no conception of perfect solidity; and every phenomenon in nature appears to disprove its existence. The minutest corpuscle we can operate upon, is still capable of a minuter division, and the parts into which it divides possessing the common nature of the corpuscle which has produced them, must necessarily, it is added, be capable of a still farther division; and as such divisions can have no assignable limit, matter must necessarily and essentially be divisible to infinity. This argument, indeed, is highly plausible; but it was soon obvious that it leads to a pure nonentity of a material world: for that which is essentially unsolid, and infinitely divisible, must at length terminate in nothing. And hence, Leibnitz, about half a century, and Boscovich, about a century afterwards, attempted to amend the system, by contending, as indeed Zeno is supposed to have done formerly, that matter has its ultimate atoms or monads, as they were denominated by Leibnitz, from the language of Pythagoras, beyond which it is altogether indivisible; and that these ultimate atoms or monads are simple unextended points, producing however the phenomena of extension by their combination, and essentially possessed of the powers of attraction and repulsion.

The object of Boscovich, in framing this hypothesis, was to get rid of the difficulty of imagining the property of extension to belong to a body taken collectively, when the same is not predicated of its component parts. For this purpose he still adhered to the supposition, that matter is made up of a number of unextended points, but attempted to account for the extension, which a combination of them possesses, by resolving the very idea of that property itself into something more simple,—the resistance offered by a combination of particles to the approach of another combination of similar particles, in consequence of those particles being endued with the power of repulsion at certain distances. This would certainly produce the effect which results from the property which we usually term impenetrability; and it is from that primary property of matter that the notions of substance, figure, and bulk, included under the term extension, arise. But the ingenuity of Boscovich, though enabling us to maintain in argument the doctrine of particles mathematically indivisible, can hardly persuade us of the reality of their existence, and we shall evade the objection which may on this account be alleged against the theory of indivisible atoms, yet still possessed of extension, by considering those atoms as bodies not destitute indeed of parts, but having those parts held together by a force capable of resisting any attempt by natural means to separate them. Upon this supposition we may fairly speak of, or reason on, the ultimate particles to which the division of matter can be carried, even though they may be proved mathematically to consist of an infinite number of points. This theory, though opposed by Kant, and the more modern German schools of philosophy, was the view taken by Newton. "All things considered," observed that philosopher, "it seems probable that God in the beginning formed matter in solid, massy, hard, impenetrable; moveable particles, of such sizes and figures, and with such other properties, and in such proportion to space as most conduced to the end for which he formed them."

But the strongest proofs which we posses of the correctness of the hypothesis, that matter consists of a finite number of indivisible particles, are derived from the discoveries of modern chemists, relative to the definite proportions in which substances combine; from the laws which have been observed to regulate the phenomena of crystallization, and from the researches of Professor Mitscherlich into the correspondence which frequently exists between the crystalline form of compound bodies, and the number of their constituent atoms; and which he has denominated *isomorphism*. Of the first we shall speak in the next article, the others we shall notice under their respective heads. In addition, we may observe, that this theory is strongly supported by one or two exceedingly ingenious arguments deduced entirely from recent observation and experiment. In a memoir on the Finite Extent of the Atmosphere, published in the *Philosophical Transactions* for the year 1822, Dr. Wollaston has observed, that upon the supposition of the contrary hypothesis, the matter composing our atmosphere ought to extend throughout space. For being a permanently elastic fluid, the force of repulsion which continually tends to keep its particles asunder, must operate wherever any portion of air exists; consequently, if it be infinitely divisible, there ought to be no limit to its extent. On this supposi-

tion all space would be filled with matter, and in that case, the different heavenly bodies would attract to themelves an aerial fluid of more or less density in proportion to their respective bulks. The occultation of Venus, by the body of the sun, or the passage of that planet behind it in May, 1821, afforded the means of ascertaining whether this were the case with respect to the sun; for from the well-known optical phenomena of refraction, the apparent position of a body seen through any one of these atmospheres, would differ from its real position in a degree proportionate to the density of that atmosphere. A series of observations was made, both on its approach to and departure from the sun, and in no one instance was the apparent position of the planet found to be in the least degree affected by any refraction of the rays proceeding from it through a solar atmosphere; thus, justifying the conclusion that none existed of that density, which would have surrounded it, had matter been uniformly diffused throughout space, or in other words, been infinitely divisible. On the other hand, if we suppose the atmosphere to be made up of atoms, or to consist of a finite number of elementary particles, incapable of farther division, the force of repulsion can only separate them up to that point; and that force being diminished in proportion to the increase of the rarity of the medium, in other words, of its elevation from the surface of the earth, it follows that at a certain height, the power of gravity which tends to draw the particles towards the earth, would counterbalance that of repulsion, which acts in a contrary direction, and thus render them stationary, and consequently at that distance would be found the limit of the atmosphere.

Dr. Faraday, in a paper on the Existence of a Limit to Vaporization, in the *Transactions* for 1826, has corroborated this view of the question, by showing that there is a certain temperature, and for most bodies not a very low one, at which all evaporation of their substance ceases, the force of gravity belonging to their component particles counterpoising that of the mutual repulsion which tends to destroy their cohesion. This, observes Dr. Daubeny, would not be the case if the matter of which those bodies consisted were infinitely divisible; for however low their temperature might be (always supposing it to be above the point of absolute privation of heat), in other words, however feeble the power of repulsion, yet, as it would be exerted on parts of matter which are by the very supposition so minute as to possess the counteracting force of gravity in a still weaker degree, it ought to continue to produce some effect.

From all the concurrent arguments we seem to be justified in concluding that a limit is to be assigned to the divisibility of matter, and consequently that we must suppose the existence of certain ultimate particles, stamped, as Newton conjectured, in the beginning of time by the hands of the Almighty with permanent characters, and retaining the exact size and figure, as well as the other more subtle qualities and relations which were given to them at the first moment of their creation. Whether, according to the doctrine of some philosophers, these particles all belong to one primary kind of matter, the πρωτη ὑλη of the Greeks, impressed with certain distinct properties, or with various modifications of the same property; or whether, as others imagine, several elementary kinds of matter were originally produced, the intermixture and union of which are the causes of the infinite variety of appearances that diversify the face of creation, is a question to which no decisive answer can be returned. The present state of our knowledge of nature would incline us to the latter opinion; while, the revolutions to which that knowledge is continually subject, forbids us positively to assert that the progress of discovery may not ultimately establish the truth of the former.

Atomic Theory; the expression which is used to designate the laws of the definite proportions in which chemical combination takes place between bodies.

It is a circumstance which could hardly fail to have attracted observation as soon as any progress had been made in chemical manipulation, that the same body, however produced, is at all times composed of the same ingredients in exactly the same proportions. Thus, if several portions of the substance known by the name of carbonate of potass, be analyzed, they will all be found to consist of certain quantities of carbonic acid and potass; and if the quantities of those elements, which enter into each be compared, the proportion of the weight of the acid to the weight of the alkali will invariably be that of 22 to 48, whether the portion of the compound examined be a pound, an ounce, or a grain. It would also have been observed, that the same body frequently united in more than one proportion with another; and that the different compounds thus produced by the union of the same substances in different proportions, often bore no relation whatever to each other, but seemed each to belong to a distinct class of bodies. One of them, for instance, might possess acid properties, the other be tasteless and inert; or one might be combustible, while the other supported or extinguished flame. It could not fail also to be remarked, that in those cases in which the chemical properties of the combining bodies were in a manner effaced by their union, they would not unite in every proportion; in other words, the number of combinations of which they were susceptible did not appear to be indefinite, that in fact there are few instances in which it exceeded four or five; and that when the ingredients were presented to each other in intermediate quantities, the resulting compounds were not in reality distinct, but mixtures of two or more of the combinations known to exist. This point being ascertained, it was natural that the relation which the several compounds, consisting of the same ingredients, might bear one to the other should be a subject of inquiry; and it is only surprising that men of science should so long have overlooked the simple law by which the combinations between bodies are now shown to be regulated.

The first step towards the determination of this point was made by a German chemist, of the name of Wenzel, who, in a work published at Dresden, in 1777, remarked, that when two neutral salts decomposed each other, the resulting compounds were exactly neutral. Thus, if sulphate of silver and nitrate of barytes were to be brought into contact, decomposition would ensue, and there would result two neutral salts—nitrate of silver and sulphate of barytes; and if to the nitrate of silver thus obtained, phosphate of soda were added, we should then have phosphate of silver and nitrate of soda, both also neutral. Hence the same quantity of sulphuric acid, that was combined with the silver in order to form sulphate of silver, is exactly sufficient to enter into combination

with the barytes, so as to form sulphate of barytes; and the same quantity of nitric acid, which was originally united with the barytes to form nitrate of barytes, exactly suffices to combine with the silver for the formation of nitrate of silver. Now 19.75 grains of dry sulphate of silver is made up of 5 grains of sulphuric acid, and 14.7 grains of oxide of silver; or, in other words, 5 grains of acid and 14.7 of oxide are requisite to form a neutral compound, or to neutralize each other's properties; and 16.5 grains of nitrate of barytes consists of 6.75 grains of nitric acid, and 9.75 of barytes. It is found, when these substances are presented to each other in these quantities, that the union of the sulphuric acid and the barytes produces a neutral compound, as does also that of the nitric acid and the silver; hence we conclude that 5 grains of sulphuric acid just suffice to neutralize 9.75 of barytes; and 6.75 grains of nitric acid to neutralize 14.75 of silver. These results are exhibited more conveniently in the following form.

Original Compounds.

5 grs. sulph. acid neutralize 14.75 grs. ox. sil.
6.75 nit. acid . . . 9.75. barytes

Resulting Compounds.

5 grs. sulph. acid neutralize 9.75. barytes
6.75 nit. acid . . 14.75. ox. sil.

Here we perceive that exactly 5 grains of sulphuric acid neutralize, or form a neutral compound with, both 14.75 grains of oxide of silver, and 9.75 of barytes; hence, 14.75 grains of oxide of silver are equivalent in their power of combining to 9.75 grains of barytes. We also observe, that just 6.75 grains of nitric acid are required to neutralize the same quantities of those bodies; it follows, therefore, that 6.75 grains of nitric acid are equivalent to 5 grains of sulphuric acid.

Now it is found that if the 21.5 grains of nitrate of silver (consisting of 6.75 grains of nitric acid, and 14.75 of oxide of silver) which result from the above process, be presented to 7.5 grains of dry phosphate of soda (containing 3.5 grains of phosphoric acid and 4 of soda) decomposition ensues, and the 4 grains of soda just suffice for the 6.75 grains of nitric acid, and the 14.75 grains of oxide of silver for the 3.5 of phosphoric acid; which we may express more conveniently thus.

Original Compounds.

6.75 grs. nit. acid neutralize 14.75 grs. ox. sil.
3.5 . phos. acid . . 4 soda

Resulting Compounds.

6.75 gr. nit. acid neutralize 4 grs. soda
3.5 . phos. acid . . 14.75 ox. sil.

Combining these results with those exhibited in the preceding table, we perceive at once that

$\left.\begin{array}{l}\text{6.75 grains nitric acid}\\ \text{5 . . . sulphuric}\\ \text{3.5 . . phosphoric}\end{array}\right\}$ are equivalent to each other in their power of combining;

and that

$\left.\begin{array}{l}\text{9.75 grains barytes}\\ \text{14.75 . . ox. silver}\\ \text{4 . . . soda}\end{array}\right\}$ are equivalent to each other in their power of combining.

Proceeding upon this principle, Richter, a Prussian chemist, endeavoured to ascertain the relative capacities of saturation belonging to the several acids and bases, and to express them by a scale of numbers. The results of his researches were published in the form of a table, but they were by no means so correct as those of Wenzel, whose accuracy indeed is remarkable. This table contains the equivalent quantities of some of the earths and alkalies which would be requisite to neutralize 1000 parts of sulphuric acid, and also the equivalent quantities of some other acid, which would be capable of producing the same effect as that quantity of the sulphuric. It might naturally have been expected that two inquiries would be suggested by this table of Richter's; the one with a view of ascertaining, first, whether the same law which had been established with respect to a few of the acids and bases held good generally throughout nature, and particularly where two or more combinations between one body and another existed; and secondly, whether, if such were the case, any relation could be traced between the different combining quantities of those substances which entered into combination in more than one proportion. But it was not until several years had elapsed that any attempt was made to determine either of these facts. It is, indeed, unquestionable, that so early as 1789, Mr. Higgins, in his *Comparative View of the Phlogistic and Anti-Phlogistic Theories*, published in that year, distinctly states, that one ultimate particle of sulphur, and one of oxygen constitute sulphurous acid, and one ultimate particle of sulphur and two ultimate particles of oxygen, sulphuric acid; and, moreover, that in the compounds of azote and oxygen, the ingredients are to each other in the respective proportions of 1 to 1, 2, 3, 4, and 5; but, it is evident, from the slight mention which he makes of this relation, that he was hardly aware of its importance.

In the year 1808, Mr. Dalton published the first volume of his *New System of Chemical Philosophy*, at the conclusion of which he announces as a general fact, that when two bodies combine, the union takes place betwixt their component particles in the proportion of 1 of the first to 1 of the second, 1 of the first to 2 of the second, 1 to 3, and so on. Hence, from the relative weight of the elements, constituting any given compound, that of their ultimate atoms may, with certain limitations, be inferred; and therefore, when either of the same ingredients occurs in a known proportion in other bodies, the number of its atoms present in them may admit of being determined. Two years afterwards, he published the second part of his System, in which he confirmed these views by a mass of facts derived from an accurate examination of the compounds of oxygen with other bodies; and, by the investigations of other chemists, they have been extended to all classes of chemical compounds whatever. It will at once be evident, that these doctrines of Mr. Dalton's comprehend two distinct, though mutually related propositions; whether it be true that the proportions in which bodies combine follow any numerical law, and secondly, whether, if such be the case, the circumstance may be accounted for, by supposing the union to take place between the atoms that constitute the substances in question, and that in each, the atoms are characterized by a difference of weight. The first point is a question of fact, which can only be established by observation, and which, so far as that observation has hitherto extended, is invariably found to occur. It would obviously exceed our limits to give any very detailed exemplification of its correctness; we shall therefore confine ourselves to the

following instances, which are derived from bodies whose composition has been sufficiently and accurately determined. To the different substances are prefixed the numbers, denoting the relative weights of the proportions in which they combine to form the compound marked; and the symbol + is used merely as a short and convenient substitute for the words *combined with*.

Oxygen and Hydrogen.

1 hydrogen + 8 oxygen, form water.
1 .. + 16 .. .. deutoxide of hydrog.

Oxygen and Carbon.

6 carbon + 8 oxygen, form oxide of carbon, (or carbonic oxide.)
6 .. + 16 .. .. carbonic acid.

Oxygen and Sulphur.

16 sulphur + 8 oxygen, form hypo. sulph. acid.
16 .. + 16 .. .. sulphurous acid.
16 .. + 24 .. .. sulphuric acid.

Oxygen and Nitrogen.

14 nitrogen + 8 oxygen, form protoxide of nitrog. (or nitrous oxide.)
14 .. + 16 .. .. deutoxide of nitrog. (or nitrous gas.)
14 .. + 24 .. .. hyponitrous acid.
14 .. + 32 .. .. nitrous acid.
14 .. + 40 .. .. nitrous acid.

Hydrogen and Sulphur.

1 hydrogen + 16 sulphur, form sulphuretted hydrog.
1 .. + 32 .. .. bisulphuretted hydr.

Hydrogen and Carbon.

2 hydrogen + 6 carbon, form sub-carburetted hydr.
2 .. + 12 .. .. carburetted hydrogen. (or olefiant gas.)

The same relation is also found to exist in combinations of compounds of simple bodies; thus:

Potass and Sulphuric Acid.

48 potass + 40 sulphuric acid, form sulphate of potass.
48 .. + 80 .. .. bisulphate of pot.

Potass with Oxalic Acid.

48 potass + 36 oxalic acid, form oxalate of potass.
48 .. + 72 .. .. binoxalate of potass.
48 .. + 144 .. .. quadroxalate of pot.

It is also found to extend to combinations of salts and sulphurets (or sulpho-salts.)

Now, if we but for a moment examine these results, we shall perceive that the proportion of oxygen which invariably combines with the substances mentioned is 8, or a multiple of 8; and that the proportions of hydrogen, carbon, and sulphur, are respectively, either 1, 6, and 16, or some multiple of those numbers. We observe also that we may extend the same principle to those bodies which Richter extended to their primary compounds, and Wenzel to the combinations of those compounds. We remarked above, that the quantities of two substances, which by combining together, saturate or neutralize each other, are equivalent in their power of combination; that, for instance, 14.75 grains of sulphate of silver are equivalent to 5 grains of sulphuric acid, those quantities exactly saturating each other. Also, that the quantities of two or more substances, each of which combines with and saturates the same quantity of a third substance, in other words, which are both equivalent to that third quantity, are equivalent to each other: thus, 5 grains of sulphuric acid, and 6.75 grains of nitric acid are equivalents, for they will both combine with and neutralize either 14.75 grains of oxide of silver, or 9.75 grains of barytes; and for the same reason, these two last-mentioned quantities are also equivalents. The term *chemical equivalent*, then, implies that proportion of a body which is necessary to act upon another body, the circumstances of chemical affinity being such as to permit action to take place, it being invariably found that the proportions are always the same for one body, whatever other body it be compared with. Hence, if a particular number be arbitrarily taken to represent the quantity of any one substance which is requisite in order that that substance may be able to enter into combination, and be called its *equivalent*, then the equivalents of other substances may be expressed by numbers, each number bearing the same proportion to the first number, that the combining quantity of the body it represents bears to the combining quantity of the substance to which we have assigned that first number. This was the principle on which Richter proceeded, and by the application of which he formed his table; and a slight examination of the results of combinations which we have given above will show, that by assuming 1 as the arbitrary number, to represent hydrogen, the numbers attached in the following table to those simple substances which occur in those results represent their chemical equivalents; other simple substances are also inserted, which do not enter into the preceding investigations, but whose numbers have been ascertained in a similar manner.

Chemical Equivalents, referred to Hydrogen as 1.

Hydrogen	1	Sulphur	16
Carbon	6	Calcium	20
Oxygen	8	Sodium	24
Lithium	10	Iron	28
Phosphorus	12	Potassium	40
Nitrogen	14	Molybdenum	48

Now we may perceive, that the numbers representing the chemical equivalents of all the above bodies are multiples of that of hydrogen, which is both the lightest body known, and that of which the combining quantity is the smallest; indeed, that they are all multiples of twice that number, and most of them of four times. The same observation is found to apply to the equivalent numbers of all the elementary substances known, although, indeed, according to Berzelius, it fails in one or two instances.

It may, then, be considered as a fact sufficiently established by experiment, that the different proportions in which bodies combine, do follow a numerical law, and the question naturally arises, how this circumstance may be accounted for. This can only be effected on the supposition of matter being divisible into a definite number of ultimate atoms, and consequently furnish an additional argument in favour of that hypothesis; for even if the facts, which we have detailed, be not irreconcilable to the contrary one, they are, at least, in no degree accounted for by them. Be it observed, at the same time, that the truth of the facts in question will not be at all affected, whatever be the manner in which we may attempt to account for them; they are established beyond all doubt.

If matter be infinitely divisible, no reason can be assigned why bodies should unite in certain proportions, and not in others; we should rather expect, that, as their smallest conceivable portions differ in

quantity only, and not in quality, from the largest, they should all possess the same affinities, and that, consequently, the number of combinations taking place between different substances, should be as infinite, as are the parts into which they themselves admit of being separated.

But, on the other hand, if we admit the finite divisibility of matter, and, consequently, the existence of ultimate particles or atoms, we must necessarily suppose that each distinct elementary substance is composed of atoms differing from those of every other substance in point of density or weight, and that the chemical union of bodies is nothing more than a combination between their ultimate atoms. On these suppositions we are enabled to account for the regularity with which those combinations take place. By referring to the table which we have given above, it will be perceived that there are two different combinations of oxygen with hydrogen; of which 1 part, by weight, unites in the one case, with 8 parts of oxygen to form water; and in the other, with 16 parts of oxygen to form deutoxide of hydrogen. Let us suppose, that in the first combination there are the same number of atoms in each of the combining bodies, or that each single atom of the hydrogen unites with each single atom of oxygen; it follows, that the atom of oxygen must be eight times as heavy as the atom of hydrogen, in other words, that the weight of the former must be to that of the latter in the proportion of 8 to 1; for, otherwise, the weights of a collection of the same number of atoms of each would not be in that proportion, which, however, we see is the case. We may account for the second combination, in which the proportion of oxygen is twice as great as in the first, by supposing, in this case, that two atoms of oxygen combine with each single atom of hydrogen. We therefore see, that if it be admitted that the first case of combination is that in which the combining bodies unite atom to atom, it must necessarily follow, that if we represent the weight of the atom of hydrogen, or its atomic weight, by 1, that of oxygen will be 8, and if we call the atomic weight of oxygen 1, we must express that of hydrogen by ⅛, or the corresponding decimal of .125, whichever may be most convenient. But it is by no means certain, from the relative combining weights of these elements, that they do unite atom to atom in the first case of combination; and if they do not, the relative weights of the atom of each, which we have deduced upon that supposition, will not be correct. It is just as possible, that the second case of combination is that in which the substances combine atom to atom; and if we suppose such to be the case, it is evident that the atomic weight of oxygen will be to that of hydrogen in the proportion of 16 to 1; and that we may explain the first case of combination by supposing two atoms of the hydrogen to combine with each single atom of oxygen. These observations may be more conveniently represented in the following manner; it will be apparent that the proportions of the ingredients will be equally well expressed by

2 hyd. + 16 oxy., where 2 atoms hyd. unite with 1 atom oxy.
1 hyd. + 16 oxy., where 1 atom hyd. unites with 1 atom oxy.

as by the mode which we first adopted, and in which we stated the composition thus,

1 hyd. + 8 oxy., where 1 atom hyd. unites with 1 atom oxy.
1 hyd. + 16 oxy., .. 1 atom hyd. .... 2 atoms oxy.

For it will be observed, that the proportion of the elements in each combination is the same in both forms; that denoted by 2 hyd. + 16 oxy. being the same with that expressed by 1 hyd. + 8 oxy. The reason that two different inferences as to the relative weight of the combining substances are drawn from each same proportion, is, as we see, that those inferences are deduced upon certain suppositions, with respect to the mode in which the union takes place; and each combination being liable to two such suppositions, is susceptible of two inferences. Hence, where a substance combines with another in several proportions, all that we are sure of is, that only one of them can represent the atomic weight, and in choosing that one, we must be guided by other considerations derived from a general review of the compounds which it contributes to form. The relative weight of the atoms of oxygen and hydrogen is a subject of disagreement among chemists at the present day, in consequence of some supposing the union between atom and atom to take place in the first combination, or that by which water is formed, and others referring it to the second, or that producing the deutoxide of nitrogen. We have seen that both these suppositions are equally possible; and that the necessary consequence of the one is to establish the relative atomic weights of oxygen and hydrogen to be 8 and 1, that of the other 16 and 1. The latter is the view adopted by Berzelius and Gay-Lussac; the former prevails almost universally among British chemists. Similar differences exist as to other substances, nitrogen, for example. Thus, if we suppose the proportion standing first in the list of combinations of nitrogen with oxygen, which we have given in our table, to be that in which the combining bodies unite atom to atom, the weight of the atom of nitrogen will be represented by 14, and that of oxygen by 8; and in the other combinations the union will take place between 1 atom of nitrogen with respectively 2, 3, 4, 5 atoms of oxygen. But both Berzelius and Mr. Dalton are of opinion, that the most simple of the combinations of nitrogen and oxygen, or that in which they unite atom to atom, is the second in our list, or that producing nitrous gas; and accordingly they infer that the atomic weight of nitrogen is to that of oxygen as 14 to 16, or the latter being 8, the former is 7. The composition of the combinations of those substances will then be as follows:

14 nit. + 8 oxy. nitrous oxide; 2 atoms nit. to 1 atom oxy.
7 nit. + 8 oxy. nitrous gas; 1 atom nit. to 1 atom oxy.
14 nit. + 24 oxy. hyponitrous acid; 2 atoms nit. to 3 atoms oxy.
7 nit. + 16 oxy. nitrous acid; 1 atom nit. to 2 atoms oxy.
14 nit. + 40 oxy. nitric acid; 2 atoms nit. to 5 atoms oxy.

The opposite opinion is, however, that which is more generally maintained; and, according to that, the numbers representing the relative atomic weights of nitrogen and oxygen are 14 and 8. In the determination of the numbers to be used to denote the equivalent quantities of the substances in the table which we have already given, it appeared natural when a substance entered into combination in several proportions, to select the least of them; but as we have seen, particularly in the case of the combinations of oxygen and hydrogen, we were by no means certain that in so doing we should obtain the real combining proportion of that substance, and the one of which all the others were multiples. The determination of the number representing the equivalent, as of that denoting the atomic weight of any sub-

stance, depends entirely upon which of its combinations be considered to be that in which the bodies unite atom to atom; and the same number will stand for both. When a body combines only in one proportion, it is assumed, unless it can be proved to be otherwise, that they unite atom to atom, and hence, that their relative weights will represent those of their atoms. A variety of considerations usually operate to determine the choice of the simplest proportion in which a body combines for the purpose of ascertaining its equivalent quantity or atomic weight, which it would be totally out of place to enter into here on the present occasion; we shall, therefore, only observe, that in Dr. Thomson's elaborate *First Principles*, our readers will find the subject fully investigated in detail.

It is evident, therefore, that with the limitations which we have mentioned, the relative weights of the atoms of all the elementary bodies, as well as their chemical equivalents, may be expressed by a scale of numbers. The same principle may be extended to their compounds; for instance, as we suppose water to be formed by the combination of several atoms of oxygen, uniting atom to atom with an equal number of atoms of hydrogen; the compound, thus formed, must consist of the same number of *compound atoms*, if we may use the expression, every one of which will be composed of one atom of each of the combining bodies; and the weight of the atom of hydrogen being 1, and of that of oxygen 8, the weight of the compound particle of water, or, as by an extension of the meaning of the term, it is called the atomic weight of water, will be 9. For a similar reason, the weight of an atom of deutoxide of hydrogen must be 17; for in this case, for two atoms of oxygen are supposed to unite with every single atom of hydrogen, and the weight of the compound particle of the deutoxide which is thus produced, must therefore be 1 added to twice 8, or 17. In a similar manner, the atomic weight of nitrous oxide will be found to be 22, that of nitrous gas 30, hyponitrous acid 38, nitrous acid 46, and nitric acid 54. Similarly, the relative atomic weight of a compound of any two substances, may be ascertained by adding together the weights of the number of atoms of each, which enter into combination; and this principle will, of course, extend to the combinations of these compounds. For instance, the atom of sulphuric acid, will, by reference to its composition in the table which we have given above, be seen to be 40; and that of potass is 48, this body being formed by the combination of 1 atom of potassium, whose weight is found to be 40, with 1 of oxygen; hence the atomic weight of sulphate of potass is 88, and that of the bisulphate, in the composition of which 2 atoms of sulphuric acid combine with each single atom of potass, must necessarily be 128. In its crystallized form this last salt contains a quantity of water; each particle of it, in fact, is formed by the union together of 2 atoms of acid, 1 of potass, and 2 of water; consequently the atomic weight of the compound must be 146. It will also be perceived, that the same numbers which express the relative atomic weights of two bodies, will also denote their *chemical equivalents*, as we have termed their relative combining weights. For if they represent the comparative weight of atoms, and if bodies combine atom to atom, these numbers must, as already stated, represent the ratio in which bodies combine and saturate each other; hence, indeed, the name *combining weights*, given to them by Dr. Young. Thus, if 16 represent an atom of sulphur, and 1 an atom of hydrogen, and if sulphur and hydrogen unite atom to atom, then 16 parts (whether grains or pounds) of sulphur ought to saturate 1 part of hydrogen, and thus form 17 parts of sulphuretted hydrogen; and the number 17 should also be the atomic weight and combining quantity of that gas. This is true; for we find that 17 parts of sulphuretted hydrogen enter into combination with 56 of sulphuret of potassium. This last number is the atomic weight of sulphuret of potassium, it being composed of an atom of sulphuret, the weight of which is 16, and an atom of potassium, which is 40.

When we speak of the atomic weight of a body, we do not, of course, mean to say that its ultimate atom actually weighs so much, but that the relation which its weight bears to that of the atom of some other body, is expressed by the number used. Consequently we must take some other body as a standard, and assume some number to represent its atomic weight. The choice of both is perfectly arbitrary; Thomson, Wollaston, and Berzelius, refer all substances to oxygen, on account of its capability of combining with every other simple body; and the first assumes its atomic weight to be 1, the second 10, and the third 100. This difference is of little moment, as it merely involves the necessity of expressing in the one case by whole numbers, what is done in the other by fractional parts.

Mr. Dalton, on the other hand, prefers taking hydrogen for his standard, and in this he is followed by a number of other chemists. The advantage is, that all other known bodies being heavier than hydrogen, their atomic weights may be expressed by means of only an ascending scale of numbers. The number assumed as the atomic weight of hydrogen by those who take it for a standard, is 1.

Either of these standards will answer every purpose. In order to convert a number on the hydrogen scale into the corresponding one on the oxygen scale, it is only necessary to divide the former by 8; and if that on the oxygen scale be multiplied by 8, the product will be that of the hydrogen scale. The comparative merits of these two scales must be settled by each person according to the facility he finds in applying them to his purposes; we may however observe that the former would possess a decided advantage, if it should be found to be invariably true, that the combining proportions of all other bodies were multiples of that of hydrogen.

Our limits have compelled us to abstain, in the present article, from many interesting points of inquiry, intimately related to the atomic theory, though not forming an essential part of it; we may instance the principle observed by Guy-Lussac, to regulate the combination by volume of gaseous bodies, and which is termed the law of volumes;—the facts discovered by Mitscherlich, relative to the correspondence existing between the crystalline form of compound bodies and the number of their constituent atoms, which he has denominated *isomorphism*—and the phenomena of *isomerism* and *merorganization*. We shall, however, speak of these on a future occasion. Those of our readers who wish to investigate the subject more fully, we cannot do better than refer to the latest edition (1832) of Dr. Turner's *Elements*; Dr. Daubeny's *Introduction to*

the Atomic Theory, and the before-mentioned work of Dr. Thomson.

Atony; a want of due tension, or a relaxation of the system.

Atra Bilis; a disposition to a dark biliary secretion, usually visible through the whole frame.

Atrip, in nautical language, is applied either to the anchor or sails. The anchor is said to be atrip, when it is partially discharged.

Atrophy is a deficient nourishment of the body. There are many diseases in which the body becomes daily more lean and emaciated, appears deprived of its common nourishment, and for that reason, of its common strength. It is only therefore in those cases in which the emaciation constantly increases, that it constitutes a peculiar disease; for when it is merely a symptom of other common diseases, it ceases with the disease, as being merely a consequence of great evacuations, or of the diminished usefulness or imperfect digestion of the nourishment received. But when emaciation or atrophy constitutes a disease by itself, it depends upon causes peculiar to this state of the system. These causes are,—permanent, oppressive, and exhausting passions, organic disease, a want of proper food or of pure air, exhausting diseases, as nervous or malignant fevers, suppurations in important organs, as the lungs, the liver, &c. Copious evacuations of blood, saliva, &c., are also apt to produce this disease, and on this account, lying-in women, and nurses who are of slender constitution, are often the subjects of this complaint. This state of the system is also sometimes produced by poisons. A species of atrophy takes place in old people, in whom an entire loss of strength and flesh brings on a termination of life without the occurrence of any positive disorder. It is known as the *marasmus senilis,* or atrophy of old people. Atrophy is of frequent occurrence in infancy, as a consequence of improper, unwholesome food, exposure to cold, damp, or impure air, &c., producing a superabundance of mucus in the bowels, worms, obstructions of the mesenteric glands, followed by extreme emaciation, which state of things is often fatal, although the efforts of the physician are sometimes successful, when all the causes of the disease have been previously removed. A local state of the same kind is sometimes produced in single limbs, by palsies, or the pressure of tumours upon the nerves of the limb, &c., and is generally curable by removing the cause.

Attack, in the *Military Art.* Every combat consists of attack and defence: the first, with few exceptions, will always be the most advantageous: hence, an experienced general chooses it, if possible, even in a defensive war. Nothing is more ruinous than to lose its advantage; and it is one of the most important objects to deprive an adversary of it, and to confine him to the defensive. The attack is directed according to the condition and position of the enemy, according to the purpose of the war, according to place, time, and circumstances. Many modes and combinations are allowable. The simplest and most unexpected form will be the best. On the dexterity and courage of the troops, the correct and quick execution of the attack will depend. Those attacks are the best, where all the forces can be directed in concert towards that point of the enemy on which his position depends. If he be beaten at this point, the resistance at others will be without concert or energy. Sometimes it may be of advantage to attack the weakest side of the enemy, if in this way a fatal blow can be given to him; otherwise, an attack at this point is not advisable, because it leads to no decisive results, leaves the stronger points to be overcome afterwards, and divides the force of the assailant. In most cases, the enemy may be defeated if his forces can be divided, and the several parts attacked in detail. The worst form of attack is, that which extends the assailing troops in long, weak lines, or scatters them in diverging directions. It is always unfortunate to adopt half measures, and not aim to attain the object at any price. Instead of saving power, these consume it in fruitless efforts, and sacrifices are made in vain. Feeble assaults and protracted sieges are of this ruinous character. The forms of attack in a battle, which have been used from the earliest times, are thus divided by the tacticians. 1. The parallel, which is the most natural form, and which the troops attacked strive as much as possible to preserve it; for as long as they can do so, they retain their connection and the power of applying their force as occasion may require; but, for this very reason, it is not the best form of attack, because it leaves the defensive party too long in possession of his advantages. 2. The form in which both the wings attack, and the centre is kept back. Where the front of the enemy is weak (the only case in which it is practicable), it appears, indeed, overpowering. 3. The form in which the centre is pushed forward, and the wings kept back, will hardly ever be chosen, on account of several evident disadvantages. 4. The famous oblique mode, where one wing advances to engage, whilst the other is kept back, and occupies the attention of the enemy by pretending an attack. Epaminondas, if not the inventor of this form, knew, at least, how to employ it to the greatest advantage. Whilst the wing which remained behind engaged the attention of the enemy, he increased continually the strength of the one advancing, which he led against the flank of the enemy, with a view of overpowering it by numerical superiority. The success of this mode is almost certain, provided the enemy takes no measures against it. In our times, this form of attack is executed in another way:—whilst engaging the enemy, his flank is surrounded by detached corps, which fall, at the same time, on his rear. If he suffers this quietly, he is vanquished. The enemy's attention is kept occupied, during such operations, mostly by feigned attacks or movements, which are called in general, *demonstrations,* and are intended to keep him in error concerning the real object. Field fortifications are attacked with columns, if possible, from several sides at the same time, and with impetuosity. Commonly, the artillery breaks a way beforehand, destroys the works, and disturbs the garrison.

Attaint, in the *Veterinary Art,* a diseased limb, proceeding from a blow.

Attalicæ Vestes; a species of golden cloth.

Attenuants; a peculiar class of medicines, among which we may particularly place the aromatics, and also the alkaline salts. When viscid humours are to be evaporated from the chest, then elecampane and balsam of Peru may advantageously be employed.

Attenuation; the act of reducing a body into minute particles.

Attic, in *Architecture.* An upper story, or false order, of dwarfish proportions, placed on the summit of a real order, is called an attic story, or an attic

order; probably, because, from concealing the roof, it imitated the buildings of Attica, which were without, or with very flat roofs, for there are no attics existing in the ruins of Athens. In the best ancient examples the attic order or story was generally formed of pilasters, with capitals and entablatures composed without regard to the rules which govern the regular orders. In modern examples, termini, terminial busts, and even caryatides, have been used to form the attic of a building. The Roman architects employed the attic to great advantage over the entablatures of their triumphal arches. The solidity of their forms compensated for the voids below, and formed appropriate pedestals for the chariots and horses with which they were crowned. Their divisions formed also excellent panels for sculpture or inscriptions. If an attic be introduced in an architectural design, it should be so managed as not to appear an after-thought, or that the building had been raised since its first erection; it should bear a just proportion to the other parts, and is better when the building has a proportionate basement or stylobate, than when the columns or antæ of the principal order are standing on the ground. If windows be required, they should be either circles or as nearly square as possible. An oblong parallelogram also looks better in an attic order than a perpendicular aperture of the same dimensions. The attics of Sir William Chambers, at Somerset House, and of Mr. Soane, in the Lothbury Court of the Bank of England, are cited as good examples of attics.

Attic Base. This is a peculiar kind of column, or support, employed both in the Doric and Ionic orders.

Attitude, in *Painting* and *Sculpture;* the position or gesture fitted for the display of some grace, or beauty, or other quality of form. As attitude is of first importance to the artist, and of primary utility in grouping, a knowledge of anatomy is absolutely necessary to prevent the introduction of constrained or impossible attitudes. An attitude may be fixed or transitory, meditated or accidental, and should be applied with propriety to the action represented, or the figure will be unnatural. Attitudes are usually arranged by the aid of a wooden automaton, called a "lay figure." One of the most striking examples of accidental attitude on record, is that of Mr. Nollekin's celebrated bathing figure, justly considered as the best which he ever executed, and which we are informed he derived from his undraped female sitter rising suddenly from a couch, on which she had been sitting in the artist's study. At the end of the last century, the celebrated Lady Hamilton began to practise; and, as every art begins with imitation, she imitated, with great talent, the attitudes of antique statues in many large towns of Europe; and Sir William Hamilton could say that he possessed, in his wife, a whole collection of antiques. Her dress was a simple tunic, fastened with a ribbon tight under the breast, and a shawl. With these she imitated all the different draperies. Mr. Rehberg drew her attitudes, and published them in London. On the continent of Europe, this art has been carried to much perfection by Mrs. Hendel-Schütz, who exhibited the most beautiful attitudes, copied from the Greek, Egyptian, Italian, and German styles of art. But she was not satisfied with imitations: she invented many attitudes, which were declared, by all the critics of the day (amongst whom was Goëthe), some of the finest productions of art. Her attitudes have been drawn and published by Peroux and Ritter (Frankfort, on the Maine, 1809). There has been also a male artist of the same kind, Mr. von Seckendorf (called *Patrick Peale*), who accompanied his exhibitions with lectures. The same sort of exhibition has lately been produced by Mr. Ducrow.

Attollens; a series of muscles sometimes called levatores and elevatores.

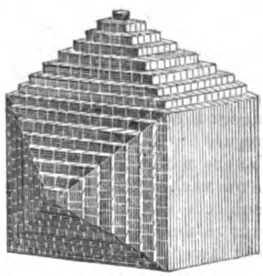
Attraction; the name by which we express the tendency which all bodies invariably have to move towards each other. If two masses of matter be placed at any distance from each other, and be uninfluenced by any external force, they will be observed to move towards each other, as if they each possessed a certain virtue by which it is capable of drawing the other towards it. It is also found that, under the same circumstances, this effect increases as the masses or quantities of matter in the bodies increase. If the quantity of matter be double, the bodies will move towards each other with a double speed: if the quantity of matter be increased in a threefold proportion, the speed of their mutual approach will be also increased in a threefold proportion; and so on. It is likewise found, that the energy of this effect is increased in a certain proportion as the distance between the bodies is diminished; the more closely the bodies approach, the more rapid will be their motions: but this increase of rapidity is not in proportion to the decrease of the distance, but in the proportion of the decrease of what arithmeticians call the square of the distance. This attraction of bodies for one another is called Gravitation, or Gravity, which see. Gravitation, then, may be considered as a power constantly acting at sensible distances upon masses of matter, or visible combinations of the ultimate invisible atoms of bodies. It is a universal property of matter in its operation, and is found to depend upon the *quantity* of matter alone, without regard to its nature. When occurring between bodies which are situated at considerable distances from each other, it is one of the most extraordinary subjects which the human mind can contemplate; and, although the manner in which it operates, and the laws which it follows, are now well understood, it proceeds from secret agencies which the human mind has never yet been able to detect. It is found to exist among all the great bodies of the universe, and to be the power which, restrained by that of inertia, preserves the planetary bodies in their orbits, and presides over their movements; and it is owing to the same general principle that the moon raises the water of the ocean, and forms what we call the tide. We have also numerous instances of it which come more immediately within our own powers of observation. A stone unsupported by the hand is drawn directly to the earth; and a plummet suspended near the side of a mountain inclines towards it in a degree proportioned to the magnitude of the mountain; as Dr. Maskelyne ascertained by a series of experiments upon the mountain Shehalion, in Scotland. If the plummet were let fall near the mountain, it would still fall to the earth, because, although drawn towards the mountain, it is much more strongly drawn towards the earth, the earth containing by far the greater quantity of matter.

When the power of attraction operates at very minute, insensible distances, it is termed Cohesion. It acts upon the ultimate invisible atoms of bodies

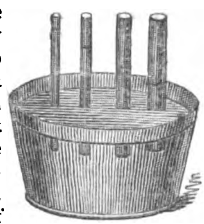
tending to unite them into one mass, and is the power which keeps together the particles of bodies in the state of a solid, and resists any attempt to separate them. The results of attraction, as relating to the texture and forms of matter, are influenced by the circumstances under which it has taken place. Sometimes the particles are, as it were, indiscriminately collected; at others, they are beautifully arranged, giving rise to regular and determinate figures: in this case, bodies of the same composition almost invariably affect the same form; hence, we are often enabled to infer the composition of a substance from accurate inspection of its external or mechanical characters. The regular polyhedral solids thus resulting from the influence of attraction upon certain kinds of matter, are usually called *crystals;* and are said to be produced by the process of *crystallization.*

Hence, it would seem that attraction, in causing the atoms to cohere, so as to form solid masses, seems not to act equally all around each atom, but between certain sides or parts of one, and corresponding parts of the adjoining ones. The fluor-spar of Derbyshire crystallizes in cubes, as does also common salt. Nitre assumes the form of a six-sided prism, and sulphate of magnesia that of a four-sided prism. The basaltic pillars of the Giant's Causeway in Ireland, and in the Isle of Staffa, are natural crystalline arrangements of particles. The observation made by Gahn, that when a piece of calcareous spar was carefully broken, all its particles were of a rhomboidal figure, induced Bergman to suspect the existence of a primitive nucleus in all crystallized bodies.

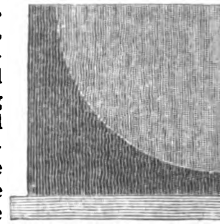
The beautifully symmetrical arrangement which exists naturally in the form of crystalline bodies is shown in the mathematical figure annexed, representing a cube having a series of decreasing layers of cubic particles upon a portion of its faces.



The attraction of cohesion is sometimes attended with a very peculiar effect. If water be poured into a glass vessel and allowed to attain a state of rest, it will be observed to be more elevated at the sides than at the centre, owing to the attraction between the sides of the vessel and the water. If a tube with a very fine bore be immersed in water, the liquid will be elevated in the inside above its level on the outside. This effect takes place because the attraction between the sides of the tube and the water, which tends to draw up the water at the sides, is sufficiently powerful at the same time to lift up that in the middle. If a tube with a bore of half an inch be tried, this effect will not take place, at least to so visible an extent, for the surface presented by the sides of the tube, and consequently its power of attraction, does not increase in the same proportion as the surface of the water. The accompanying illustration will serve to exhibit the ascent of the water in tubes of different bores.



Another mode of exhibiting the effects of capillary attraction may now be adverted to. It consists in the use of two glass plates, hinged together like a book, as is shown in the engraving, and partially separated on one side. On placing the plates in any coloured fluid, it will be found to ascend in a curved line; the fluid rising highest at the side where the plates are nearest, and as such obeying precisely the same law as in the former case.



We have considered attraction as operating in two principal points of view,—at sensible distances on masses or combinations of atoms, of which species is that case to which we have given the name of *gravitation;* and at insensible distances upon the atoms themselves, so as to keep them together in one body. When it operates at insensible distances, to unite particles of different bodies, so that they cannot be separated by any ordinary means it is termed *chemical attraction*, or, simply affinity, and is exemplified in the solution of a lump of sugar or alum in water. For a particular account of its effects, and the laws which they follow, see CHEMISTRY and ATOMIC THEORY.

There are yet two other species of attraction to notice—those of electricity and magnetism. The attraction of electricity is produced by a disturbance of the electrical equilibrium, and is usually exemplified for experimental purposes by rubbing a glass tube, and then bringing it into the neighbourhood of any light pendulous body. The same effects on a large scale, are shown by the electrical machine. See ELECTRICITY.

The attraction of magnetism is exemplified in the approach of iron filings to a magnet; like that of electricity, it acts at sensible distances upon masses, and must therefore be arranged in the same class as gravitation, though so far as we can at present judge, by no means resulting from the same causes. See MAGNETISM.

ATTRACTIVES; a peculiar species of remedies which act by promoting external discharge.

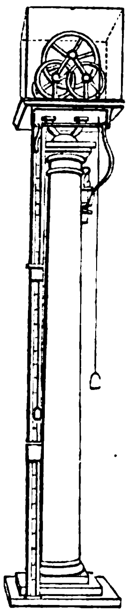
ATTRAENTS; digestive medicines.

ATTRIBUTES; the peculiar properties of bodies. Thus, gravitation is an attribute of matter, whatever be its form. Infinite extension is also, though erroneously, considered an universal attribute.

ATTRIBUTES, in *Painting* and *Sculpture,* mean any adjunct to a figure or group, which is characteristic of the principal subject.

ATWOOD'S MACHINE. A very useful apparatus under this title, employed by the Editor in his public lectures, should have a place in the present department of our work. Its great cost prevents its general use, but it is of the greatest importance for illustrating the doctrine of accelerated motion. The space described, and the acceleration gained by bodies which descend freely towards the earth, has been often attempted to be proved by means of direct experiments; but the resistance of the air, which opposes a considerable and fluctuating impediment, and the difficulty of measuring the time of descent when falling bodies have acquired a great degree of velocity, which soon increases beyond the power of our senses to estimate, have always rendered the re-

sult of such experiments precarious; but by means of the instrument recommended in the accompanying engraving every difficulty is obviated.



It consists of a tall mahogany column, not less than ten feet in height, resting on a base, and supporting a series of friction wheels. The friction wheels again support a large central roller. To the left of the figure is seen a wooden rod, graduated so that the descent of any falling body may readily be indicated in feet and inches.

Now, if we suppose the weights on the opposite ends of the line to be exactly balanced, no motion would occur, as they would be exactly in a state of equilibrium; but if we add, in the slightest degree, to the weight on the left hand, then, by destroying the equilibrium, we shall produce motion, and the body will descend. The weights employed for this purpose are heavy, and but little acted on by the air or any extraneous circumstance; but as the slightest increase of weight will produce motion, we may thus make it apparent to the eye.

Atypos; any thing irregular in its form, either in medicine or anatomy.

Avant-Guard; the corps which precedes the march of an army.

Avante, in the old medical nomenclature, the same with hypochondriasis.

Aubin; a defective gait in a horse.

Auditoria Arteria; the internal auditory artery which goes off from each side of the arteria basilaris to the organ of hearing, and accompanies the auditory nerve, having first furnished several small branches to the membrana arachnorides.

Auditorius Meatus; the passage that conveys the air to the auditory nerve. It leads from the lower anterior part of the concha to the tympanum, and is partly bony, partly cartilaginous: the bony part is the longest, and forms the bottom; the rest is cartilaginous, and makes the external opening or orifice of the canal. These two parts form a canal of about three-fourths of an inch long, slightly tortuous, and wider in some parts than in others. On the membranous covering of the cartilaginous part we observe the yellow bodies, supposed to be the glandulæ ceruminis. The bony part of the meatus is nearly horizontal and straight; the cartilaginous part only is curved and winding, which should be observed when a syringe is used to inject any thing with into the ear.

Auditorius Nervus; the auditory nerve. The seventh pair of nerves are called auditory nerves; so are the sympatheticæ minores. This seventh pair of nerves runs into the os petrosum, and is there divided into the portio mollis, which is spent upon the labyrinth of the ear, and distributed to the auditorius meatus internus, passing to the vestibulum cochleœ, and the portio dura, which goes out by the aqueduct, between the mastoid and styloid processes, passes through the parotid, becomes a cutaneous nerve, and communicates with the upper maxillary. On these nerves, no covering from the dura mater can be traced.

Avellane; an heraldic cross placed on the sovereigns' globe.

Aventuræ; a species of military exercise.

Avenue, in *Architecture;* a way to an access or approach; a long walk of columns, arcades, statues, trees, &c. used for the decoration of an approach to a palace or mansion. The avenue, in the hands of a man of taste, is susceptible of great variety and beauty of design.

Averti, in *Horsemanship*, a regular step or motion.

Auger; an instrument for boring holes.

Auges; two points in a planet's orbit; the one denominated the apogee, the other the perigee.

Augette, in military engineering, the tube for igniting a mine.

Augmented. This term in *Music* means, when applied to a note, an interval of three chromatic degrees.

Augmentation, in *Heraldry*, a particular mark of honour, borne either on an escutcheon, or a canton; as argent, a hand, gules, borne by every baronet who cannot claim higher honour.

Augury was at one time considered a science of the first importance; it has now however taken its proper rank among the absurd superstitions which disgraced the darker, nay, even the most enlightened periods of antiquity. The intestines were generally torn quivering with life from the still sensitive victim, and formed the principal instrument in the hand of the soothsayer or priest. Thanks, however, to the diffusion of general knowledge in every class of society, those disgusting exhibitions of cruelty and priestcraft have now passed away, and we advert to it but as an historical record.

Aulos; a Grecian measure of length equal to the stadium.

Aume; a measure of capacity, employed on the Continent, equal to thirty-five English gallons.

Auncel Weight. This is a term much employed by the old writers. It relates both to the implements for weighing and the mode of effecting a sale. The auncel was a balance with several scale pans, and its use was prohibited by statute. To sell by auncel means with advantage to the dealer.

Aune; a measure of length employed on the Continent. It varies considerably in different parts of Europe. Dr. Kelly, in his *Cambist*, makes it equal to 46.38 English inches. In other parts it is equal to nine-tenths of our ell.

Avoirdupois; a weight having sixteen ounces to the pound, in distinction to Troy weight, which has only twelve. The following is a tabular view of this weight:—

16 drams make	1 ounce.		4 quarters make	1 cwt.
16 ounces	1 pound.		20 cwt.	1 ton.
28 pounds	1 quarter.			

drs.	*ozs.*				
16 =	1 =	*lbs.*			
256 =	16 =	1	*qrs.*		
7168 =	448 =	28 =	1 =	*cwt.*	
28672 =	1792 =	112 =	4 =	1	*ton.*
573440 =	35840 =	2240 =	80 =	20 =	1

5760 Troy grains make 1 pound Troy, and 7000 Troy grains 1 pound Avoirdupois; hence 175 pounds Troy are equal to 144 pounds Avoirdupois.

A very valuable comparative estimate of the relative values of British and Foreign Avoirdupois weights

has been published by Mr. Adcock, of which we may now give the substance.

Names of Places.	AVOIRDUPOIS WEIGHT.	
	Names of Weights.	Number equal to 112lb. Avoird.

Aura signifies an exhalation or vapour. The old chemists mean by it a certain fine and pure spirit, found in every animal and vegetable body; but so subtle as only to be perceptible to us by its smell.

Aurea Alexandrina, in *Pharmacy*, a compound opiate confection, much in repute among the ancient physicians. It was considered as a powerful alexipharmic, or antidote to poison.

Aurens; an ancient gold coin, varying very much in its value in different parts of the Roman empire, equal to about eighty sesterces.

Auriculæ Judæ is a sort of fungus, which grows on elder trees. Its internal use is hardly considered safe, but a decoction in milk has been much esteemed as a gargle in cases of quinsey.

Auricula; the external part of the ear, which is divided into the upper part, called pinna, and the lower soft part, called lobus, or lobulus. The pinna is divided into several eminences and cavities: the eminences are the helix, called also capreolus; antihelix; tragus, called also antilobium; and antitragus. The helix is the large border round the ear, or the exterior compass of the ear: so called because of its tortuosity. The anti-helix is the large oblong eminence surrounded by the helix. The tragus is the like anterior protuberance, opposite to the lobe, below the fore part of the helix, which in the aged is often covered with hairs. The anti-tragus is the posterior protuberance below the inferior extremity of the anti-helix; the name of a muscle which acts only upon the cartilage of the ear.—The cavities are the scapha, on the inside of the helix; the cavitas innominata, or fossa navicularis, at the anterior upper part of the anti-helix; the concha, which is situated under the anti-helix, divided by a septum, which is a continuation of the helix; and the meatus auditorius externus.

The auricula is composed chiefly of cartilage, which gives and preserves its shape. It has the advantage of being variable, for there are certain small muscles, called helicalis major and minor, tragicus, and anti-tragicus, which are peculiar to the ear; they act only upon the cartilage, and contribute to direct it towards sound; or, by giving a greater tension, to increase its intensity.

The external ear is fixed to the cranium, not only by the cartilaginous portion of the meatus, but also by the ligaments, viz. the anterior, which is fixed by one extremity to the root of the apophysis zygomatica of the os temporis, close to the corner of the glenoid cavity, and by the other extremity to the anterior and superior part of the cartilaginous meatus. The posterior ligament is fixed by one end to the root of the mastoid apothysis, and by the other to the posterior part of the convexity of the concha, so that it is opposite to the anterior ligament. There is also a kind of superior ligament, which seems to be only a continuation of the aponeurosis of the frontal and occipital muscles.

Auricolla, a substance with which goldsmiths solder gold.

Auriga, in *Astronomy*, the Waggoner; a constellation in the northern hemisphere. In Ptolemy's Catalogue there are 14 stars numbered; in Tycho's, 27; in Helvelius's, 40: in the Britannic Catalogue, 66. This is one of the 48 asterisms, mentioned by all the ancient astronomers; and is represented by the figure of an old man in a kind of sitting posture, with a goat and her kids in his left hand, and a bridle in his right. Besides the Hoedi, this constellation includes another of the stars which the ancients distinguished by peculiar names, that is, Capella, and Almathœa Capra, which is the bright one near the shoulder, and supposed to be the mother of the Hoedi, and the nurse of Jupiter. The Hoedi, or the two stars in the arm of Auriga, were regarded by the ancients as affording presages of the weather: and they were so much dreaded, on account of their power over storms and tempests that succeeded their rising, that they were said to shut up the navigation of the sea at this season. When the day of their peculiar influence was passed, the ancients celebrated a festival with sports and games, under the denomination of "Natalis Navigationis." Germanicus calls them stars unfriendly to mariners; and Virgil joins them with Arcturus, mentioning their setting and rising as circumstances of the most important presage. To the same purpose all the ancient critics represent a part of the constellation Auriga, if not the whole of it, as deserving particular attention, and as much an object of terror as the blazing Arcturus.

Aurigraphus; an illuminator, or writer in golden characters.

AURIS; the term by which anatomists express the ear. The ear is usually divided into the external and internal. By the external, is meant all that lies without the external orifice of the meatus auditorius in the os temporis. By the internal, all that lies within the cavity of this bone; the orifice of which is called cyar. The arteries of the external ear come anteriorly from the arteria temporalis, and posteriorly from the occipitalis. The veins are branches of the external jugulars. The portio dura of the auditory nerve having passed out of the cranium through the foramen stylo-mastoidæum, gives off a branch, which runs up behind the ear. The second vertebral pair send also a branch to the ear, the ramifications of which communicate with those of the other branch from the portio dura. The bones of the ear, called malleus, incus, orbiculare, and stapes, are placed in the cavity of the tympanum, immediately on the inside of the membrana tympani. The malleus is joined by its handle to the membrana tympani, and its round head rests on the incus, the long leg of which rests on the os orbiculare, which is fixed to the fore part of the stapes, the sole of which rests on the hole called fenestra ovalis.

The use of the external ear is to collect sounds, and to render their impression on the other organs of hearing most perfect. This is evident from those who have their ears cut off being obliged to use a horn, or some other means to assist them in hearing: all animals, as deer, hares, &c. whose ears have much motion, always direct them so as to meet the sound. See EAR, SOUND, and ACOUSTICS.

AURISCALPUM; a surgical instrument employed to operate on the ear.

AURORA BOREALIS, or Northern Lights. We often see in the north, near the horizon, usually a short time after sunset, a dark segment of a circle, surrounded by a brilliant arch of white or fiery light; and this arch is often separated into several concentric arches, leaving the dark segment visible between them. From these arches, and from the dark segment itself, in high latitudes, columns of light, of the most variegated and beautiful colours, shoot up towards the zenith, and, sometimes, masses like sheaves of light are scattered in all directions. The appearance is then splendid; and its increasing beauty is announced by a general undulation of the masses of light. A kind of fiery coronet is afterwards formed about the zenith, by the meeting of all the columns of light, resembling the knob of a tent. At this moment the spectacle is magnificent, both for the multiplicity and beauty of the columns which the aurora presents. (See Maupertuis *De la Figure de la Terre*, Paris, 1738.) The light, after this, grows fainter and more tranquil. This faintness and tranquillity, however, are only temporary, for the phenomena are soon repeated in all their beauty—the oscillation of the columns of light, the formation of the corona, and the like, though with a thousand variations. At length, the motion wholly ceases, the light is collected about the northern horizon, the dark segment vanishes, and nothing is left but a strong brightness in the north, which is lost in the dawning day. These brilliant appearances are also attended, in high latitudes, with loud noises, described as resembling the hissing and crackling of fire-works. This appearance has received the name of *northern light*, because, on account of our position on the earth, we see it only about the north pole. A similar appearance, *aurora australis*, was seen about the south pole, in 1773, by Cook's sailors, between 58° and 60° S. lat., and later travellers have observed the same. These phenomena ought, therefore, properly to be called *polar lights*. Philosophers are of different opinions as to the cause of the aurora. It is, however, satisfactorily ascertained to be within the region of our atmosphere. The satisfactory demonstration of the agency of electricity in the production of thunder and lightning, has occasioned the application of its principles to the solution of other phenomena, and in some instances it applies more plausibly than any other existing explanation. Such is particularly the case with some of those luminous appearances that occasionally enliven our atmosphere; effects which have always been, and still continue amongst its most mysterious phenomena.

The aurora borealis, or northern light, is a phenomenon of this kind, whose appearance so exactly resembles some of the effects of artificial electricity, that those who have had the opportunity of comparing it with them, can entertain no doubt that their causes are identical. When electricity passes through rarefied air, it exhibits a diffused luminous stream, which has all the characteristic appearances of the northern lights. There is the same variety of colour, and intensity; the same undulating motion, and occasional corruscations; the streams exhibit the same diversity of character, at one moment minutely divided in ramifications, and at another beaming forth in one body of light, or passing in distinct broad flashes; and when the rarefaction is considerable, various parts of the stream assume that peculiar glowing colour which occasionally appears in the atmosphere, and is regarded by the uninformed observer with astonishment and fear. There is, therefore, little doubt that the natural phenomenon is occasioned by the passage of electricity through the upper regions of the atmosphere. The lowest estimate that has been made of the distance from the earth's surface at which it occurs, is that of Mr. Cavendish, who states that distance to be 71 miles; now, at 70 miles, the air is 1,048,576 times more rare than at the surface of the earth; and this is a degree of rarefaction beyond the power of any air-pump yet constructed. These circumstances tend almost to a demonstration, that the light of the aurora is produced by the same means as the light of electricity; but there are other characteristics of that remarkable phenomenon that still remain unexplained.

Dr. Halley has described very fully the appearance of a remarkable aurora, and has collected together a variety of observations that may serve as a history of its phenomena; he ascribed its production to the same influence as that which causes magnetism; and the observations of Mr. Dalton prove that the luminous beams of the aurora is really that of the dipping-needle. Signior Beccaria conceives that the phenomena of magnetism are occasioned by a constant natural circulation of the electric fluid from north to south, originating from several sources in the northern hemisphere. The aberration of the common centre of these currents from the north point, he supposes, may cause the variation of the needle; the period of this declination from the centre may be the period of the variation; and the obliquity of the current the cause of the dip of the magnetic needle.

The northern lights are at present very rarely

visible here; about thirty years since they were frequently observed, and on one occasion their appearance was remarkably brilliant, and has been minutely noticed by Mr. Dalton. An extract from his description will convey a general idea of an effect we have but rarely an opportunity to observe.

"Attention was first excited by a remarkable red appearance of the clouds to the south, which afforded sufficient light to read by, at eight o'clock in the evening, though there was no moon, nor light in the north. Some remarkable appearance being expected, a theodolite was placed to observe its altitude, bearing, &c.

"From 9½ to 10 P. M., there was a large, luminous, horizontal arch to the southward, almost exactly like those we see in the north; and there was one or more concentric arches northward. It was particularly noticed, that all the arches seemed exactly bisected by the plane of the magnetic meridian. At half-past 10 o'clock, streamers appeared very low in the S. E., running to and fro, from W. to E.; they increased in number, and began to approach the zenith, apparently with an accelerated velocity; when, all on a sudden, the whole hemisphere was covered with them, and exhibited such an appearance as surpasses all description. The intensity of the light, the prodigious number and volatility of the beams, the grand intermixture of all the prismatic colours in their utmost splendour, variegating the glowing canopy with the most luxuriant and enchanting scenery, afforded an awful, but at the same time the most pleasing and sublime spectacle in nature. Every one gazed with astonishment; but the uncommon grandeur of the scene only lasted about one minute; the variety of colours disappeared, and the beams lost their lateral motion, and were converted, as usual, into the flashing radiations; but even then it surpassed all other appearances of the aurora, in that the whole hemisphere was covered with it.

"Notwithstanding the suddenness of the effulgence at the breaking out of the aurora, there was a remarkable regularity in the manner. Apparently, a ball of fire ran along from east to west, and the contrary, with a velocity so great as to be barely distinguishable from one continued train, which kindled up the several rows of beams one after another: these rows were situate before each other with the exactest order, so that the bases of each row formed a circle crossing the magnetic meridian at right angles; and the several circles rose one above another in such sort, that those near the zenith appeared more distant from each other than those near the horizon, a certain indication that the real distances of the rows were either nearly or exactly the same. And it was farther observable, that during the rapid lateral motion of the beams, their direction in every two nearest rows was alternate, so that whilst the motion of one row was from E. to W., that in the next was from W. to E.

"The point to which all the beams and flashes of light uniformly tended, was in the magnetic meridian, and as near as could be determined, between 15 and 20 degrees of the zenith. The aurora continued, though diminishing in splendour, for several hours. There were several meteors (falling stars) seen at the time; they seemed below the aurora, and unconnected therewith."

When the northern lights are visible in this country, they are said to appear chiefly in the spring and autumn, and usually after a period of dry weather; they do not refract the light of the stars, which are often distinctly seen through the luminous arch or beams. They are seen more rarely in countries nearer the equator, but occur almost instantly during the long winters, in the polar regions, and with a lustre of which we can form but a faint conception.

In the Shetland isles they are called "merry dancers," and are the regular attendants of clear evenings, giving a diversity and cheerfulness to the long winter nights. Their first appearance is at twilight, just above the horizon; they have at first no particular brilliance or motion; but, after some time, break forth into streams of refulgent light, whose Protean columns gradually assume every possible variety of form and shade of colour; frequently covering the whole visible hemisphere; which then presents the most brilliant spectacle imagination can conceive.

In Hudson's Bay, the refulgence of the aurora is stated to be frequently equal to that of the full moon. In the northern latitudes of Lapland and of Sweden, their brilliance is so remarkable and constant, as to enliven the path of the traveller during the whole night. In the north-eastern parts of Siberia they are also described as moving with incredible velocity; and clothing the sky with a most brilliantly luminous appearance, "resembling a vast expanded tent, glittering with gold, rubies, and sapphires." This phenomenon is said to be accompanied by a loud hissing or crackling noise, so terrific, that when the fox-hunters, on the confines of the icy sea, are overtaken by it, their dogs lie close to the ground, and refuse to move until the noise has passed. That a noise of this kind occasionally accompanies the northern lights, has been testified by several observers, and amongst others, Mr. Nairne and Mr. Cavallo; the last says, he has heard it distinctly on several occasions. This effect is the most extraordinary of all that accompany this phenomena, and if established as a fact, is perfectly unaccountable; for, from the extent of the country over which the aurora is frequently seen, it is certain that it must occur at a very considerable height above the earth's surface; and though the calculations on this subject differ remarkably, yet the very lowest estimate gives an elevation, at which, according to the known principles of philosophy, there exists no medium capable of transmitting sound.

An aurora has been sometimes observed near the south-pole, which seems to favour Beccaria's idea, that its cause is the circulation of a fluid. Its appearance is similar to that of the northern light, but without the same diversity of colour.

The beams of the aurora appear to converge towards the zenith, and their summits seem narrower than their bases; but this, as was observed by Dr. Halley and Mr. Cavendish, is merely an optical illusion; and it has been shown by Mr. Dalton, that the beams are really cylindrical, and parallel to each other; and that the distance of their bases from the earth, is equal to, or probably greater than, the length of the beams; and he has calculated that these beams are 75 miles long, and 7½ miles diameter.

AURUM; gold, the most valuable of all the metals. It is of a reddish-yellow colour, soft texture, not sonorous, but exceedingly ductile and malleable. (See GOLD.)

AURUM POTABILE; tincture of gold, a cordial liquor with leaf gold in it.

AURUM FULMINANS; thundering gold, a precipitate of gold, so called because of the explosion which it makes by a gentle attrition.

AURUM HORIZONTALE; a mercurial medicine of a red colour.

AURUM MOSIACUM, or MUSICUM; a composition to lay on a colour like brass or copper.

AUSTER; the south wind.

AUSTERE is in general applied to a rough astringent taste, united with that of sourness. It is identical with acerbi.

AUSTRAL SIGNS; the six last signs in the zodiac, so called because they are on the south side of the equinoctial.

AUSTRALIS PISCES; a constellation of the southern hemisphere, being one of the forty-eight constellations mentioned by the ancients, not visible in our latitude. The stars in Ptolemy's Catalogue are 18; and in the Britannic Catalogue 24. Formahaut, a star of the first magnitude, is in the mouth of this fish.

AUSTRALIZE; a disposition to point towards the south; and as opposite magnetic poles attract each other, it will be obvious that what we call the north pole of the magnet, is the austral or southern pole.

AUSTRO AFRICUS, in *Meteorology*, the south-southwest point, or wind.

AUTOMATON. Under the article ANDROIDES, our readers will find an account of a very curious and perfect automaton, and we now purpose continuing our account of self-moving machines. In the first place, however, it may be advisable to notice some of the earlier attempts at constructing automata. The flying dove of Archytas, mentioned by Aulus Gellius, is the earliest self-moving engine of which we have any record; and this, as well as the flying chair of Dr. Hook, may, in all probability, be classed with the speaking head of Friar Bacon, and the no less wonderful impositions contrived by the dealers in oracles during the darker ages of the world. Coming, however, to a later period, we find that Louis XIV. was passionately fond of automata, and devoted the early years of his life to their construction. One piece of apparatus constructed by this ingenious scion of royalty, is worthy of record.

It represented a lady proceeding to court, in a small chariot drawn by two horses, and attended by her coachman, footman, and page. When the machine was placed at the end of a large table, the coachman smacked his whip, the horses started off with all their natural motions, and the whole equipage drove on to the farther extremity; it would now turn at right angles in a regular way, and proceed to that part of the table opposite to that which the prince sat, when the carriage stopped, the page alighted to open the door, and the lady came out with a petition, which she presented with a curtsey to the bowing young monarch; the return was equally in order. After appearing to attend the prince for a short time, the lady curtsied again, and re-entered the chariot, the page mounted behind, the coachman flourished his whip, and the footman, after running a few steps, resumed his place.

M. Droz, of La Chaux de Fonds, in the province of Neufchatel, also executed some curious pieces of mechanism. One of these was a clock, presented to the king of Spain, to which pertained, among other curious contrivances, a sheep that imitated the bleating of that animal, and a dog, watching a basket of fruit, that barked and snarled when any one offered to take it away, and a variety of moving human figures. Mr. Collinson informs us, that when he was at Geneva, Droz, the son of the former, showed him an oval gold snuff-box, about 4½ inches long, 3 broad, and 1½ thick, which was double, with an horizontal partition; one of the partitions contained snuff, and in the other, upon opening the lid, there sprang up a very small bird, of green enamelled gold, perching on a gold stand. This minute curiosity, being only three-quarters of an inch from the beak to the extremity of the tail, moved its body, shook its wings, opened its bill of white enamelled gold, and poured forth such a clear, melodious song, as would have filled a room, of twenty or thirty feet square, with its harmony. Another automaton of Droz's was the figure of a man, about the natural size, which held in its hand a metal style; and, by touching a spring that released the internal clockwork from its stop, the figure began to draw on a card of Dutch vellum laid under the style. Having finished its drawings on the first card, the figure rested. It then proceeded to draw different subjects on five or six other cards, which number limited its delineating powers.

To furnish our readers with a notion of the amazing accuracy with which automata may be made to delineate figures, and, indeed, perform the part of mechanical draftsmen, we annex a fac-simile of a drawing, in the possession of Mr. Fillinham, which was actually executed by an automaton figure exhibited in London.

We cannot dismiss the subject of automata without adverting to the fact that nearly all those which have yet been made for exhibition, are much fitter for the amusement of children, than as furnishing recreation for thinking beings. Of a far different character are those employed for weaving, and other mechanical manipulations. They have served to raise this country to a degree of commercial wealth, which has enabled her to fight the battles of freedom in every part of the civilized world.

AUTOPHOSPHORUS, see PHOSPHORUS.

AUTOPYRITES; a species of bread described by Galen. The word is only found in the very early books on medicine.

AUTUMN; that one of the seasons which, in the northern temperate zone, begins when the sun, in its apparent descent to the southern hemisphere, touches the equator. The end of autumn is at the time of the sun's greatest south declination, or when he enters Capricorn. According to our computation of time, the beginning of autumn is Sept. 23, when, for the second time in the year, the days and nights are

equal; and the end is Dec. 21, at the time of the shortest day. The autumn of the southern hemisphere takes place at the time of our spring. From this astronomical autumn the physical or popular autumn differs according to the climate.

AUTUMNAL EQUINOX, see EQUINOX.

AUTUMNAL POINT is called, by astronomers, that point where the equator cuts the ecliptic: the sun reaches it Sept. 23. It is said to be at the beginning of Libra, and is continually marked so, notwithstanding the point has long since receded from this constellation, and is now near the stars of the left shoulder of Virgo. It is opposite to the vernal point; therefore its ascension amounts to 180°, and its longitude also to as many, or six signs; its declination and latitude $= 0$.

AUX; an astronomical term employed to describe a portion of the ecliptic.

AWL; a sharp-pointed implement formed of the best steel.

AWME, see AUME.

AWN *of wine*, a measure which does not occur in modern commercial transactions, but is stated in the dictionaries to be equal to 360 pounds.

AWNING, on board a ship, is when a sail, a tarpauling, or the like, is hung over any part of the vessel, above the decks, to keep off the sun, rain, or wind. Awnings are made of canvass. The length of the main-deck awning is from the centre of the fore-mast to the centre of the main-mast and fore-mast. The length of the quarter-deck awning is from the centre of the main-mast to the centre of the mizen-mast; and the width answers to the breadths of the ship, at the main-mast, mizen-mast, and at the midway between. The length of the poop, or after-awning, is from the centre of the mizen-mast to the ensign-staff, about seven feet above the deck. The canvass is cut to the given breadths of the awning, allowing a few inches to hang down on each side, which is sometimes scolloped and bound. Half the diameter of the masts is cut out in the middle at each end, and lacing-holes are made across the ends, to connect one awning to another. Sometimes curtains are made to hang to the sides of the awnings, of the same length as the awnings. Their depth is taken from the sides of the awning to the gunwale. The seams and tablings are the same as those of the awnings, and lacing-holes are made along the upper tabling of the curtain, and the side tabling of the awning.

In the long-boat they make an awning, by bringing the sail over the yard and stay, and booming it out with the boat-hook.

On shore, awnings are made of common canvass; and if they be frequently wetted, ice may be preserved between them and the damp earth—so powerful is the refrigirating power of the evaporation.

AXAMENTA; choral harmony without instrumental accompaniment.

AXE; a large sized hatchet. It is much employed by the Indian tribes for the purposes of war, and many hundreds of these destructive implements have lately been manufactured in Birmingham to be sent with the "fire water" (*Anglicè*, ardent spirits), for the purpose of civilizing the aboriginals in America.

AXILLA; the arm-pit. There is a peculiar secretion from this part of the body, which in many persons is highly offensive. It is affirmed, that a cure may be effected by the use of a decoction of wild artichoke in wine.

AXILLARY ARTERY, see SUBCLAVIAN.

AXILLARY GLANDS; secreting glands beneath the arm-pits.

AXILLARY NERVE. This nerve passes beneath the arm-pit, and joins the cervical series.

AXILLARY VEIN. This, like the preceding, takes its name from the arm-pit, beneath which it runs, and dividing itself into branches, supplies the whole neighbourhood.

AXILLARY VERTEBRÆ. The second in the downward series of bones.

AXIOM, a self-evident truth, or a proposition whose truth every person receives at first sight; and to which the term is applied, par excellence, on account of its importance in the process of reasoning. Axioms are self-evident truths that are necessary, and not limited to time and place, but must be true at all times and in all places.

Thus, that the whole is greater than a part; that it is impossible for a thing both to be and not to be, at the same time; and that from nothing, nothing can arise, are axioms,

By axioms, called also maxims, are understood all common notions of the mind, whose evidence is so clear and forcible, that a man cannot deny them without renouncing common sense and natural reason.

Self-evident proportions furnish the first principles of reasoning; and it is certain, that if in our researches we merely employ such principles as these, and apply them properly, we shall be in no danger in advancing from one discovery to another. For this we may appeal to the writings of mathematicians, which being conducted agreeable to this standard, incontestably prove the stability of human knowledge, when it is made to rest on so sure a foundation. The propositions of this kind of science, have not only stood the test of ages; but they are found to be attended with that invincible evidence, which constrains the assent of all who consider the proofs by means of which they are established.

Lord Bacon proposes a new science, to consist of general axioms, under the denomination of *philosophia prima*.

Axiom is also an established principle in some art or science. Thus, it is an axiom in physics that Nature does nothing in vain; that effects are proportional to their causes, &c. So it is an axiom in geometry, that if to equal things you add equals, the sum will be equal, &c. It is an axiom in optics, that the angle of incidence is equal to the angle of reflection and refraction. In this sense the general laws of motion are called axioms; as that all motion is rectilinear, and that action and reaction are equal.

These particular axioms, it may be observed, do not immediately arise from any first notions or ideas, but are deduced from certain hypotheses; this is particularly observable in physical matters, in which, as several experiments contribute to make one hypothesis, so several hypotheses contribute to one axiom.

The axioms of Euclid are very general propositions, and so are the axioms of the Newtonian philosophy; but these two kinds of axioms have very different origins. The former appear true upon a bare contemplation of our ideas; whereas the latter are the result of the most laborious induction. Lord Bacon, therefore, strenuously contends, that they should never be admitted upon conjecture, or even upon the

authority of the learned; but, as they are the general principles and grounds of all learning, they should be canvassed and examined with the most scrupulous attention.

A modern writer distinguishes between axioms intuitive, and self-evident. The former, he says, pass through the first inlets of knowledge, and flash direct conviction on the minds, as external objects do on the senses, of all men; in the formation of the the latter, reason judges by single comparisons, without the aid of a third idea or middle term; so that they have their evidence in themselves, and though inductively framed, they cannot be syllogistically proved. If we admit this distinction, and its reasonableness must be allowed, the character of intuitive axioms will be restricted to particular truths.

Axis, in *Anatomy*, the second vertebræ of the neck.

Axis, in *Geometry*, the straight line in a plane figure, about which it revolves, to produce or generate a solid. Thus, if a semi-circle be moved round its diameter at rest, it will generate a sphere, whose axis is that diameter; and if a right-angled triangle be turned about its perpendicular at rest, it will describe a cone, whose axis is that perpendicular. The term axis is yet more generally used for a right line conceived to be drawn from the vertex of a figure to the middle of the base.

Axis *of a Circle or Sphere*, is any line drawn through the centre, and terminated at the circumference on both sides.

Axis *of a Cylinder*, is the line from the centre of the one end to that of the other.

Axis *of a Conic Section*, is the line from the principal vertex, or vertices, perpendicular to the tangent at that point. The ellipse and hyperbole have each two axes, which are finite and perpendicular to each other; but the parabola has only one, and that infinite in length. Transverse axis, in the ellipse and hyperbola, is the diameter passing through the two foci, and the two principal vertices of the figure. In the hyperbole it is the shortest diameter, but in the ellipse it is the longest. Congregate axis, or second axis, in the ellipse or hyperbola, is the diameter passing through the centre, and perpendicular to the transverse axis, and is the shortest of all the conjugate diameters. Axis, of a curve line, is still more generally used for that diameter which has its ordinates at right angles to it, when that is possible. For, as in conic sections, any diameter bisects all its parallel ordinates, making the two parts of them on both sides of it equal; and that diameter which has such ordinates perpendicular to it, is an axis: so, in curves of the second order, if any two parallel lines each meeting the curve in three points; the right line which cuts these two parallels so, that the sum of the two parts on one side of the cutting line, between it and the curve, is equal to the third part terminated by the curve on the other side, then the said line will in like manner cut all other parallels to the former two lines, viz., so that of every one of them, the sum of the two parts, or ordinates, on one side, will be equal to the third part or ordinate on the other side. Such cutting line then is a diameter; and that diameter, whose parallel ordinates are at right angles to it, when possible, is an axis. And the same for other curves of still higher orders.

Axis, in *Astronomy*. As the axis of the world is an imaginary right line conceived to pass through the centre of the earth, and terminating at each end in the surface of our sphere, about this line, as an axis, the sphere, in the Ptolemaic system, is supposed daily to revolve.

Axis *of the Earth*, is the line connecting its two poles, and about which the earth performs its diurnal rotation, from west to east. This is a part of the axis of the world, and always remains parallel to itself during the motion of the earth in its orbit about the sun, and perpendicular to the plane of the equator.

Axis *of a Planet*, is the line passing through its centre, and about which the planet revolves. The Sun, Earth, Moon, Jupiter, Mars, and Venus, it is known from observation, move about their several axes; and the like motion is easily inferred of the other three, Mercury, Saturn, and Georgian planet.

Axis *of the Horizon*, *Equator*, *Ecliptic*, and *Zodiac*, are right lines passed through the centres of those circles, perpendicular to their planes.

Axis *of a Magnet*, or *Magnetical Axis*, is a line passed through the middle of a magnet lengthwise; so that, however the magnet be divided, provided the division be made according to a plane passing through that line, the magnet will then be cut into two loadstones. And the extremities of such lines are called the poles of the stone.

Axis, in *Mechanics*. The axis of a balance or cylinder is the line upon which it moves or turns.

Axis *of Oscillation*, is a line parallel to the horizon, passing through the centre, about which a pendulum vibrates, and perpendicular to the plane in which it oscillates.

Axis *in Peritrochio*, or *Wheel and Axle*, is one of the mechanical powers, or simple machines, contrived chiefly for the raising of weights to a considerable height. See Mechanics.

Axis *of a Vessel*, is that quiescent right line passing through the middle of it, perpendicular to its base, and equally distant from its sides.

Axis, in *Optics*. The optic axis, or visual axis, is a ray passing through the centre of the eye, or falling perpendicularly on the eye.

Axis *of a Lens*, or *Glass*, is the axis of the solid of which the lens is a segment. Or the axis of a glass, is the line joining the two vertices or middle points of the two opposite surfaces of the glass.

Axis *of Incidence*, in *Dioptrics*, is the line passing through the point of incidence, perpendicularly to the refracting surface.

Axis *of Refraction*, is the line continued from the point of incidence or refraction, perpendicularly to the refracting surface, along the farther medium.

Axle, see Axis.

Axungia; the old name for hogs'-lard.

Axungia Vitri Sandiner; a salt of glass procured during fusion.

Azarum; a medicinal root employed as a specific for the farcy in horses.

Azed; another name for the large Camphor, which see.

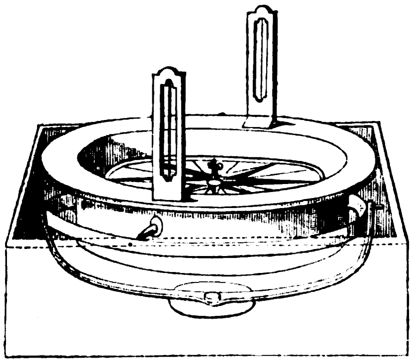
Azelfoge, in *Astronomy*, a fixed star of the second magnitude, in the Swan's Tail.

Azemech, in *Astronomy*, see Virgin's Spike.

Azimuth; an arc of the meridian, comprehended between the meridian of the place, and the azimuth circle, passing through the sun, &c.

Azimuth Circles; great circles of the spheres, intersecting each other in the Zenith and Nadir.

Azimuth Compass. The common compass, when provided with sights, may be converted into this instrument. The sights are so placed that the sun may be seen, in order to find its amplitude or azimuth. Whence the declination of the magnetic meridian from the true or astronomical meridian may be determined; those two meridians seldom coinciding.



An instrument of this description is represented in the accompanying figure, in which the sight-plates ascend perpendicularly, being furnished with a perpendicular thread or wire through the middle The ring of the gimbals rests with its pivots on the semicircle beneath, the foot of which turns in a socket, so that whilst the box remains steady, the compass may be turned round, in order to place the sights in the direction of the sun, or other celestial object. The pivots of the gimbals of this, as well as of the steering compass in general, should lie in the same plane with the point of suspension of the needle or card, for the purpose of avoiding the irregularity of its vibrations as much as possible. In the inside of the box there are two lines drawn on its sides perpendicularly down, from the points where the thread touches the edge of the box. These lines serve to show how many degrees the north or south pole of the needle is distant from the azimuth of the sun; on which account the middle of the apertures in the sight vanes, the thread, and the above-mentioned two lines must stand exactly in the same vertical plane. The use of the thread, which is sometimes omitted in compasses of this sort, is to show the degrees between the magnetic meridian and the azimuth, &c., when the eye of the observer stands perpendicularly over it. On one side of the box of the azimuth compass, there is generally a nut or stop, which, when pushed in, bears against the card and stops it; and this is done for the purpose of reading that degree, half-degree, &c., of the card which coincides with one of the perpendicular lines in the inside of the box.

Azimuth Dial; a dial whose stile or gnomon is perpendicular to the plane of the horizon.

Azoga Ships (from the Spanish *azogue*, quicksilver) were those Spanish ships, commonly called the *quicksilver ships*, from their carrying mercury to the Spanish West Indies, to extract the silver from the mines of Mexico and Peru. They were prohibited from carrying any goods except for the king of Spain.

Azote, or Nitrogen, is a permanently elastic gas, transparent, colourless, and inodorous. Its specific gravity is 0.9748; and 100 cubic inches of it weigh 30.0355 grains.

A number of processes have been given in chemical books for the preparation of azote, but they are tedious or troublesome, or both. The following is the method recommended by Mr. Donovan in his excellent work on Chemistry. Take a bottle, capable of containing a gallon (277¼ cubic inches), and fit a cork accurately to it: throw into it 22 troy drachms of the salt sold by druggists under the name of green copperas, or sulphate of iron, with half a pint of water; then pour as much water on 4½ drachms of roche lime as will slake it; and when slaked, throw it into the dissolved sulphate of iron. Cork the bottle perfectly close; and, having inverted it, immerse the neck in a vessel of water, to prevent the entrance of air. By agitating this mixture briskly during a few minutes, still keeping the neck immersed, the whole of the oxygen present in the common air, which the bottle had contained, will be absorbed; and, on removing the cork under water, a quantity of water will rush in, equal to the volume of oxygen which had been removed. The air now remaining in the bottle is pure azote; its volume is 222 cubic inches, and it may be transferred into any other vessel, by filling that vessel with water, inverting it so, that the mouth shall be in water, then getting the mouth of the bottle under the vessel, and turning the mouth upwards, water will enter and azote will rise into the receiver. The quantity of sulphate of iron and lime here directed, is just double what would be required by calculation; but the process is thus hastened.

If a burning body be immersed in a jar of azote, it is extinguished as instantaneously as if plunged into water. No animal that breathes can live in azote; and from this circumstance is derived its name, which signifies life-depriver. It is not combustible: it enters extensively into combination: it is an abundant element in animal matter; and its existence in such large quantity, is a chief distinction between the constitution of animal and vegetable matter. There is great difference of opinion as to whether oxygen and azote are merely mixed together in the atmosphere, or whether they are in a state of chemical combination. Strong arguments have been advanced on both sides, and the question remains yet undecided. It is now no longer confined to the atmosphere, but has extended to the constitution of all mixed gases.

Those who support the opinion that the two gases are chemically combined in the atmosphere, found their belief upon facts like the following:—The specific gravity of azote is less than that of the atmosphere; the specific gravity of oxygen is greater. Now, since a certain volume of oxygen is heavier than an equal volume of azote, we should expect, that if, in the atmosphere, they be merely mixed without the operation of affinity, the oxygen would at length subside to the earth; while the azote will float above it. But we know that the fact is otherwise; for air taken from the greatest elevations to which balloons ascend, affords the same relative quantities of the two gases. Atmospheric air is also of the same composition in all parts of the world. This consideration appears to favour the opinion, that between the two cases some chemical attraction subsists: but there are also considerable objections to this view of the subject.

It may be objected, that if the oxygen and azote are thus combined, some of those chemical changes ought to be observable, which indicate combination, and new properties should be evolved. But none such are discoverable; for the specific gravity of common air is the mean of the specific gravities of oxygen and azote: and its chief properties seem to be a mean of the properties of its component gases.

A view of the subject has been proposed by Dr. Dalton, which is not liable to these difficulties, although not free from objections of another kind. Dr. Dalton conceives that the repulsion which produces the elasticity of the atmosphere, does not subsist between azote and oxygen, but between azote and azote, and between oxygen and oxygen. He conceives that, with regard to oxygen, azote offers scarcely any resistance to the indefinite expansion of that gas; and that oxygen does not resist the indefinite expansion of azote. In fact, he supposes that each acts as a vacuum to the other, and that whatever pressure a particle of oxygen at the earth's surface sustains, that pressure arises solely from all the particles of oxygen above and around it, but none whatever from those of the azote; and, conversely, that a particle of azote at the earth's surface, is pressed by all the other particles of azote in the atmosphere, but not at all by the oxygen. Each gas thus sustaining only its own weight, it would expand itself, regardless of the other; both would press upon other bodies, but neither would subside according to its weight. And although, at very great heights, there might be a difference of the relative proportions of the oxygen and azote, in consequence of the great predominance of azote in the atmosphere, this could not be observed at such heights as are within our reach. He conceives that the two gases are not in any manner chemically combined.

The most obvious objection to the hypothesis of Dalton is, that were it admitted, it should follow, that by connecting a glass globe filled with oxygen, and one filled with azote, by a stop-cock, the heavier gas being underneath, the moment the communication is opened, there should be an instantaneous mixture. Dr. Dalton made the following experiment: A pint vial filled with carbonic acid, and an ounce vial of common air, were connected by a glass tube, thirty inches long and one-third of an inch bore, so that both vials were air-tight with regard to the external air, and communicated with each other through the tube. This apparatus stood vertically, the common air vial being uppermost. In one hour, the common air vial had acquired no sensible quantity of carbonic acid gas; but in three hours it had it in great plenty. Dr. Dalton adduces this experiment, to prove that the ascent of the air in the lower vessel is not attributable to chemical affinity, as none subsists between the two gases; and he infers that it favours his hypothesis. It seems to be as much an evidence against his hypothesis as for it. If each gas acted as a vacuum to the other, there ought to be an instantaneous commixture. But, to remove this obstacle, he says, that the gases meet with some mechanical obstruction, owing to their minute division, while passing each other in contrary directions. Is it conceivable, observes Mr. Donovan, that such an obstruction could exist to the transmission of two gases through a tube one-third of an inch diameter; and that, for the space of an hour, there should not have passed even the smallest quantity of the carbonic acid gas into a vacuum? This experiment seems quite fatal to the hypothesis. He has adduced other experiments, made with the same kind of apparatus, but using gases which are not known to have any direct affinity for each other; such as carbonic acid gas and hydrogen. In the mixture which took place of these two gases with each other, Dr. Dalton conceives that affinity cannot be supposed to be concerned, as they are not known to have any affinity. That conclusion may, however, be questioned. It may be very true that carbonic acid and hydrogen do not manifest any affinity for each other in their gaseous state; but it is quite certain, that the three elements concerned—carbon, oxygen, and hydrogen—have, collectively, a powerful affinity for each other, and constitute the bases of vegetable organized matter. The obstacle to the successful exertion of their affinity, is the elastic form: but a partially successful exertion may be conceived to operate so far, that the solid elements would be retained at the limits between the calorific repulsion and chemical attraction; the latter force being active in a slight degree, but not sufficiently so to effect a combination. See Nitrogen.

Azoth, in *Alchemy;* the mercurius philosophorum, or universal remedy.

Azure, in *Heraldry,* denotes the blues in the arms of any person below the rank of baron. In engraving, this colour is represented by regular horizontal lines.

Azure, in *Painting;* a light or sky-coloured blue. This word is presumed to be derived from the Arabic lazul, which has the same meaning. The fine sky colour of lapis lazuli, and the pigment made from it, called ultra-marine, are of the greatest use to painters, both in oil and water colours. It is the most costly colour which painters employ.

Azyges, in *Anatomy;* another name for the os sphenoides.

Azygos, the name of a vein situated within the thorax, on the right side, having no similar vein on the left.

Azzalum, in *Metallurgy;* a peculiar species of iron brought from China.

BAAT; a coin current in Siam, weighing about half an ounce, and is identical with the tical of the Chinese. It is also used as a weight for other bodies.

Babylonia Cura; a term used by the astrologers to signify the art of casting nativities.

Babylonian; an epithet applied to any thing belonging to astrology.

Babylonica, in *Antiquity;* a species of rich weaving, so called from the city of Balylon, where the art of weaving hangings with a variety of colours was first invented.

Bac; a kind of praam or ferry-boat.

Bacca Bermudensis, in the *Materia Medica;* the fruit of arbor sapronaria or soap-berry tree, the kernel of which, steeped in water, raises a froth, like soap.

Baccharach Wine; a wine very much resembling Rhenish; but Portzius says that it differs from it in several particulars.

Baccharis is a sweet-scented medicinal plant, growing mostly in rough and dry grounds. The roots smell like cinnamon, and are a powerful stimulant; the leaves are moderately astringent.

Bacilli are made by mixing medicine with a proper quantity of sugar, and the mucilage of gum tragacanth; and when formed into a stiff paste, it is cut into proper portions and dried. This form is adapted for medicine designed to be slowly swallowed, as demulcents.

Bacillum; a peculiar form of medicine.

Bacillum; iron instruments used in chemistry in the shape of a staff.

Back-board; a board placed in the after part of a ship to lean against, as the back of a chair. This name is also applied to an instrument for remedying distorted spine.

Back-frame-wheel; an instrument for laying cordage.

Backing *of a wall;* the building which forms the inner face of a wall, or the act of building the inner face.

Back-painting; the method of painting mezzotinto prints pasted on glass, with oil colours. See Painting.

Back *an anchor;* to carry out a small anchor to support the larger one.

Back *astern;* to manage the oars in rowing in a direction contrary to the usual method.

Back *the sails;* to arrange them for the ship to retreat or move astern, in consequence of the tide favouring her.

Backgammon; a game played with dice, by two persons, on a table divided into two parts, upon which there are 24 black and white spaces, called *points*. Each player has 15 men, black and white, to distinguish them. The word is of Welsh origin, signifying *little battle*. The following are in brief the laws of the game: 1. If a man is taken from any point, it must be played. 2. A man is not played, till it is placed upon a point and quitted. 3. If a player has only 14 men in play, there is no penalty attending it. 4. If he bears any number of men before he has entered a man taken up, and which, of course, he was obliged to enter, such men, so borne, must be entered again in the adversary's table, as well as the man taken up. 5. If he has mistaken his throw, and played it, and his adversary has thrown, it is not in the choice of either of the players to alter it, unless both parties agree to it.

Back-piece; a portion of defensive armour strapped to the back.

Back-staff; an instrument for taking the sun's altitude, so called because the back of the observer is directed towards the sun. It consists of two concentric arcs and three vanes: the arc of the longest radius is 30 degrees, and that of the shorter 60 degrees, making altogether 90 degrees, or a quadrant of the heavens.

Back-stays; a portion of the rigging of a ship.

Back-sword; a sword with one sharp edge, employed in contradistinction to a cut-and-thrust weapon.

Bacon. This species of animal flesh is employed to so large an extent as an article of food in this country, that it may be adviseable to go somewhat into detail in the processes for preparing it. When a hog is killed for bacon, the sides are laid in large wooden troughs, and sprinkled all over with bay salt: thus they are left for twenty-four hours, to drain away the blood and the superfluous juices. After this first preparation, they should be taken out, wiped very dry, and the drainings thrown away. Next, some fresh bay salt, well heated in a large iron frying-pan, is to be rubbed over the meat, until it has absorbed the moisture, and this friction repeated four successive days, while the meat is turned only every other day. If large hogs are killed, the flitches should be kept in brine for three weeks, and, during that period, turned ten times, then taken out, and thoroughly dried in the usual manner; for, unless they be thus managed, it is impossible to preserve them in a sweet state, nor will their flavour be equal to those properly cured.

Smoked bacon, one of the most relished, but indigestible, dishes of the Germans, is prepared in a similar manner to that adopted in the curing of the celebrated Westphalia hams. For the latter, however, animals which have been well fed, and allowed to roam at pleasure in the extensive moorlands of that province, are generally selected. The manner of obtaining them is nearly as follows: after the hams have been properly salted, rubbed, and wiped with dry cloths, in order to absorb all the impure juices, the cavities of the joints, as well as the bones themselves, are carefully covered with a mixture consisting of two parts of the best salt, perfectly dried, and one part of black pepper, coarsely powdered. As soon as this operation is performed, the hams are, on the same day, suspended in a chimney, where no other but wood fire is burnt, and which is usually increased during the first three days. The time of fumigation is regulated by the size of the meat, and generally extends from three to six months.

Bacon, *Fossil*. See Adipocire, for which it is but a vulgar name.

Bacule, in *Ancient Fortification;* a species of lever-trap to destroy those entering the portcullis.

Bacudometry; a mode of measuring distances.

Badiaga; a species of spongy plant; the powder of which is said to act very rapidly on livid tumours.

Badigeon; a mixture employed both by statuaries and carpenters to hide defects in their work.

Bag, in *Commerce;* a determinate quantity of goods contained in a bag, varying in size according to the article or the place, from three to four hundred weight.

Bag, in *Pharmacy;* various ingredients applied externaly, so as to act by the absorbents.

Bag, in *Farriery;* attached to the bridle-bit. It contains savin and assafœtida.

Baggage; part of the equipment of an army.

Bagnette, in *Architecture;* a small round moulding, generally enriched with laurel leaves and ribbons.

Bagnette Divinatore, see Divining Rod.

Bagpipe; a well-known wind instrument, of high antiquity among the northern nations, which has so long been a favourite with the natives of Scotland, that it may be considered as their national instrument. It consists of two principal parts: the first comprises a leather bag, which receives and holds the wind conveyed to it by a small tube, furnished with a valve, to prevent the wind from returning. The second part of the instrument consists of three pipes,—the great pipe or drone; a smaller pipe, which emits the wind at the bottom; and a third with a reed, through which it is blown. The wind is forced into the pipes by compressing the bag under the arm, while the notes are regulated, as in a flute or hautboy, by stopping and opening the holes, which are eight in number, with the ends of the fingers. It is not known when the bagpipe first found its way into

Scotland, but it is probable that the Norwegians and Danes first introduced it into the Hebrides, which islands they long possessed. Aristides Quintilianus informs us, that it prevailed in the Highlands in very early ages; and indeed the genius of the people seems to render the opinion highly probable. The attachment of that people to their music, called pibrachs, is almost incredible, and on some occasions is said to have produced effects little less marvellous than those ascribed to the ancient music. At the battle of Quebec, in 1760, while the British troops were retreating in great disorder, the general complained to a field-officer in Fraser's regiment of the bad behaviour of his corps. "Sir," said he, with some warmth, "you did very wrong, in forbidding the pipers to play this morning; nothing encourages the Highlanders so much in the day of action. Nay, even now they would be of use."—"Let them blow like the devil, then," replies the general, "if it will bring back the men." The pipers were then ordered to play a favourite martial air; and the Highlanders, the moment they heard the music, returned and formed with alacrity in the van. In a former war in India, Sir Eyre Coote, aware of the attachment of the Higlanders to their favourite instrument, gave them fifty pounds to buy a pair of bagpipes after the battle of Porto Nuovo. In Rome, at the time of Advent, the peasants of the mountains play on the bagpipe before the images of the Virgin. The music is very simple, and yet sweet; and every traveller remembers it with delight.

Bag-reef; the lowest reef in a sail.

Bail; to empty of water.

Bailbone; an heradic charge, representing a lion rampant holding a staff in his mouth.

Bails; the frames which support the awning or tilt of a boat.

Baiocco; a small coin in the Roman states, a hundred of which make a Roman crown.

Baize, in *Commerce*; a kind of coarse, open, woollen stuff, having a long nap; sometimes frized on one side, at other times not frized, according to the uses for which it is intended.

This stuff is without wale, being manufactured on a loom with two treddles like flannel. It is chiefly manufactured about Colchester and Bocking, in Essex; and in Flanders, about Lisle and Tournay, &c. This manufacture was first brought into England, together with that of says, serges, &c., by the Flemings, who fled hither from the persecution of the Duke of Alva, about the fifth year of the reign of Queen Elizabeth, and had afterwards peculiar privileges granted them by the 12 Car. II. in 1660. The exportation of baize was formerly much more considerable than it is now, as the French manufacturers have learned to imitate them, and have set up manufactures of their own at Nismes, Montpellier, &c. However, a considerable quantity of baize is still exported to Spain, Portugal, and Italy. Their chief use is for the religious, and for linings in the army; the looking-glass makers also use them behind their glasses, to preserve the tin or quicksilver; and the case-makers to line their cases.

The breadth of baize is commonly a yard and half, yard and three-quarters, or two yards; by forty-two or forty-eight in length: those of a yard and three-quarters are most proper for the Spanish trade.

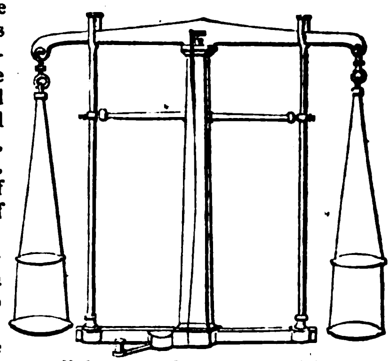
Baking is the art of converting flour, or other farinaceous substances, into bread. A proper degree of heat is an essential requisite to the baking process. When the inner arch of the oven appears entirely white, it is generally considered as sufficiently heated. But this being a fallacious criterion, the following arrangement has been recommended:—Place a handful of flour close to the aperture of the oven, and if it turn of a brown colour, the heat is then nearly of the degree required; but if it become black, or remain white, in the former case the fire must be considerably reduced; and in the latter, more fuel must be added. See Bread.

Balalaika, in *Music*, a musical instrument of the bandour kind, of very ancient Sclavonian origin; it is in common use both with the Russians and Tartars; according to the celebrated Niebuhr, it is also frequent in Egypt and Arabia. The body of it is an oblong semi-circle, about six inches in length, with a neck or finger-board of two feet. It is played on with the fingers like the bandour or guitar; but has only two wires, one of which gives a monotonous bass, and by the other the piece is produced.

Balance. This important instrument may be considered as consisting of an inflexible rod or lever, called the beam, furnished with three axes; one, the fulcrum or centre of motion, situated in the middle, upon which the beam turns, and the other two near the extremities, and at equal distances from the middle. These last are called the points of support, and serve to sustain the pans or scales. The points of support and the fulcrum should be in the same right line. The arms of the lever being equal, it follows, that if equal weights be put into the scales, no effect will be produced on the position of the balance, and the beam will remain horizontal.

If a small addition be made to the weight in one of the scales, the horizontality of the beam will be disturbed; and after oscillating for some time, it will, on attaining a state of rest, form an angle with the horizon, the extent of which is a measure of the delicacy or sensibility of the balance.

What we have now stated, will serve to illustrate the principle of the balance. Its mode of construction will be best understood by a diagram.



One of the best form is here represented. The parts are all so arranged that it can, at pleasure, be lifted off the points of support.—This is effected by aid of the two uprights, which are elevated by a small lever at the bottom. The scale pans are made of glass or platina. If the former be employed, care should be taken to prevent their being excited electrically, which would materially affect the results. This is particularly alluded to, as the Editor has seen a difference of more than half a grain produced, by merely cleaning one of the glass scale pans with a dry silk handkerchief.

In order to have a balance as perfect as possible, it is necessary to attend to the following axioms:

1. The arms of the beam ought to be exactly equal both as to weight and length.

2. The points from which the scales are suspended, should be in a right line, passing through the centre of gravity of the beam; for by this, the weights will act directly against each other, and no part of either will be lost, on account of any oblique direction.

3. If the fulcrum, or point upon which the beam turns, be placed in the centre of gravity of the beam, and if the fulcrum and the points of suspension be in the same right line, the balance will have no tendency to one position more than another, but will rest in any position it may be placed in, whether the scales be on or off, empty or loaded.

If the centre of gravity of the beam when level, be immediately above the fulcrum, it will overset by the smallest action; that is, the end which is lowest, will descend; and it will do this with more swiftness, the higher the centre of gravity be, and the less the points of suspension be loaded.

But if the centre of gravity of the beam be immediately below the fulcrum, the beam will not rest in any position but when level; and if disturbed from that position, and then left at liberty, it will vibrate, and at last come to rest on the level. In a balance, therefore, the fulcrum ought always to be placed a little above the centre of gravity. Its vibrations will be quicker, and its horizontal tendency stronger, the lower the centre of gravity, and the less the weight upon the points of suspension.

4. The friction of the beam upon the axis ought to be as little as possible; because, should the friction be great, it will require a considerable force to overcome it; upon which account, though one weight should a little exceed the other, it will not preponderate, the excess not being sufficient to overcome the friction, and bear down the beam. The axis of motion should be formed with an edge like a knife, and made very hard: these edges are at first made sharp, and then rounded with a fine hone, or piece of buff leather, which causes a sufficient bluntness, or rolling edge. On the regular form and excellence of the axes, depends chiefly the perfection of this instrument.

5. The pivots, which form the axis or fulcrum, should be in a straight line, and at right angles to the beam.

6. The arms should be as long as possible, relatively to their thickness, and the purposes for which they are intended; as the longer they are, the more sensible is the balance.

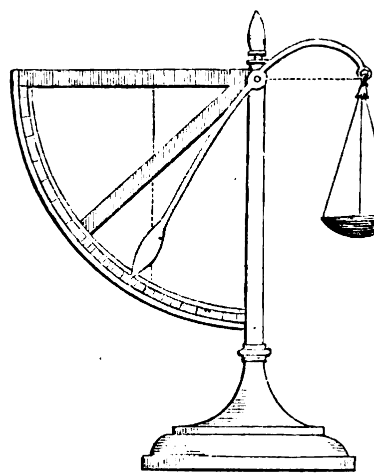
They should also be made as stiff and inflexible as possible; for if the beam be too weak, it will bend and become untrue.

7. The rings, or the piece on which the axis bears should be hard and well polished, parallel to each other, and of an oval form, that the axis may always keep its proper bearing, or remain always at the lowest point.

8. If the arms of the balance be unequal, the weights in equipoise will be unequal in the same proportion. The equality of the arms is of use in scientific pursuits, especially in the making of weights by dissection. A balance with unequal arms will weigh as accurately as another of the same workmanship with equal arms, provided the standard weight be first counterpoised, then taken out of the scale, and the thing to be weighed be put into the scale, and adjusted against the counterpoise. Or when proportional quantities only are considered, the bodies under examination may be weighed against the weights, taking care always to put the weights in the same scale; for then, though the bodies may not be really equal to the weights, yet their proportions amongst each other will be the same as if they had been accurately so.

In order to try the goodness of a pair of scales, the scales should be taken off the beam to ascertain if the beam balances without them; they should then be put on again and afterwards reversed, or each scale hung on the opposite end of the beam which it before occupied. Equal weights should then be put into the opposite scales, and these should in like manner be reversed or changed; and if the beam maintains its horizontal position under all these changes, it may be relied on as being good and perfect. The pivots or fulcrum upon which the beam turns ought to be sharp, or knife edged, as it is termed, and they should be of steel well hardened, as well as the interior of the ring in which they move: this confines the fulcrum to a minute line, and prevents friction. In beams for nice purposes, the pivots ought not to be too much elevated above the centre of gravity, for although this centre will generally be found an inch or two below the pivots in strong warehouse beams, in order to bring them to a speedy equilibrum, by which time is saved; yet, for accurate weighing, the nearer the centre of gravity is brought into the straight line that would connect the tops of the two scale eyes, and the under side of the pivot, the better; although such a beam will occasion great loss of time by its vibrating a long time before it becomes stationary.

The *steelyard balance* is an imperfect modification of the instrument we have already described. It is merely a balance of which the arms are unequal, and a weight is made to slide along the longest arm, the scale-pan being fixed at the other extremity. Now it will be obvious, by the slightest reference to the principle of this arrangement, that the expansion of the longest arm will alone render the instrument to a certain extent defective.



The *bent lever balance*, shown above, is somewhat similar in its operation to the steelyard. It acts by a fixed weight, increasing in power as it ascends along the arc of a circle, and the scale on the graduated qaudrant indicates the amount of weight.

With this instrument, one constant weight serves to weigh all others in the range of the balance, by only varying the position of the arms of the instrument, instead of varying the places or points of suspension in the arms themselves.

Mr. Patten, of Newport, in the United States, has invented a very ingenious balance for taking specific gravities. It is thus described in Siliman's *Journal:*

"One great objection to the usual balance, is the difficulty of getting the points of suspension of the scales to be at equal distances from the point of suspension of the beam; another is the friction—this alone is sufficient to prevent the substance to be weighed from containing an exact quantity of matter with the weight used; for suppose a beam to be so nicely constructed as to turn with the tenth of a grain—now to weigh 100 grains, that weight will be put into one dish, and the substance into the other, but a tenth of a grain must be added before the scale can turn perceptibly; it therefore exceeds 100 grains by the tenth of a grain, and the weights can only be equivalents when the index is at rest, which may be any where within the quantity required to turn the beam—sufficiently accurate for all common purposes, but not for weighing the gases and taking accurately specific gravities; and in analysis, where the weights are often repeated, its amount is considerable. The only accurate method is to make the weight itself the standard. To do this is the object of the beam made of steel, sufficiently strong and light. The dish is suspended, the beam itself upon an axis, the milled head of a long screw that is fitted with a shoulder and axis, and goes through the slide that traverses and carries the weight. Now, suppose it is wished to obtain ten grains; place that weight in the dish, and screw back the weight until it exactly counterbalances it. If the weight be now removed, and a quantity of the substance to be weighed is substituted until the index points to where it did at first, there will then be very nearly the exact weight, with but a small allowance for friction; for were this beam a common one, and so nicely constructed as to turn with the 100th part of a grain, it would make the distance four times greater from the point of suspension of the weight, turn with the 400th part of a grain. It is apparently an objection that 100 grains will require 400; but the fact is settled by Coulomb, that this kind of friction does not increase in an equal proportion with the weights used; that is, if with a pound in each scale, a beam turn with one grain, if there were two pounds in each, it would require two grains.

"The beam may be used as a steelyard, by screwing the weight to any number marked upon the scale; and should a greater quantity be required, then another of double the weight may be substituted."

The usefulness of having good balances for the weighing of substances, is not limited to the due performance of nice experiments, but they also save much time in weighing, when a less degree of accuracy is required. If a pair of scales, loaded with a certain weight, be barely sensible to one-tenth of a grain, it will require a considerable time to ascertain the weight to that degree of accuracy, because the turn must be observed several times over, and is very small; but if scales were used which would turn with the hundredth part of a grain or less, supposing that the weight was not required to any greater accuracy than the tenths of grains, a single tenth of a grain, more or less, would make so great a difference in the turn of the scale, that it would be seen immediately.

For the determination of the specific gravity of various substances, Muschenbrock says, he used a balance which turned within a fortieth of a grain when loaded with 200 or 300 grains; hence his balance determined the weight to the 12,000th part of the weight.

Mr. Bolton's larger balance (mentioned in *Phil. Trans.*, vol. 66), loaded with a pound, probably of the common avoirdupois, would turn with one-tenth of the grain; so that the weight is determined to the 70,000th part of the entire mass.

Mr. Bolton's small balance, capable of weighing half an ounce, turned with the hundredth part of a grain; which is the 24,000th part of the weight.

Mr. Reid's balance, mentioned in the same volume, when loaded with 55lbs. avoirdupois, turned readily with less than pennyweight, and a very distinctly with four grains, so that it determined the weight to the 96,000th part of the weight in the scale; and although so strong, is decidedly the best common balance whose performance has been recorded.

Mr. Whitehurst's balance, mentioned in the same volume, which weighed one pennyweight, was sensibly affected with the 2,000th part of a grain, or the 48,000th part of the weight.

Mr. Nicholson's balance, noticed by him in his *Dictionary of Chemistry*, when loaded with 12,000 grains in each scale, turned with the 70th part of a grain or the 84,000th part of the weight; so that this was a very good balance.

Mr. Alchorne's balance (mentioned in the *Phil. Trans.*, vol. 77), with 15lbs. at each end, turned with two grains; they were probably Troy pounds, and so the accuracy of this balance went only to the 43,200th of the weight.

Dr. G. Fordyce (in the *Phil. Trans.*, vol. 75) mentions a balance, made by Ramsden, turning on points instead of edges, which when loaded with four or five ounces Troy, could ascertain the weight to the 160th part of a grain; that is to say, the 30,400th part of the weight in the scale.

Mr. Maggellan's balance, mentioned by Nicholson in his *Dictionary of Chemistry*, with a pound in each scale, showed distinctly one-tenth of a grain, or the 70,000 part of the weight.

The Royal Society's balance, made by Ramsden, and turning on steel edges upon planes of polished crystal, is said to be sensible to the 7,000,000th part of the weight.

The comparison of the weights of different countries, as made by Mr. Tillet, with the standard mark in the mint at Paris, was made with a balance which weighed a coin of 4,608 grains, and turned with a quarter of a grain, or the 18,432d part of the weight in the scale; so that although this balance might be reckoned a good one, it was in fact inferior in accuracy to any of the above-mentioned, except Muschenbrock's.

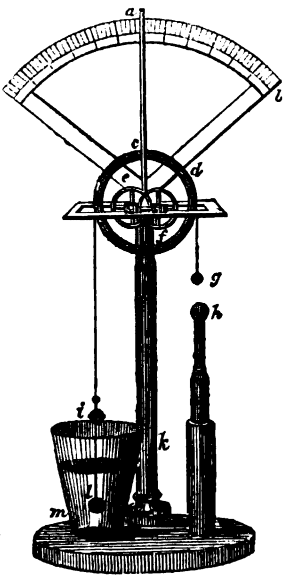
Professor Weigel, in his *Observations*, says, he used a balance which, when loaded with two marks, Cologne weight, at each end, the beam turned 1-12th of an inch with a foreign coin, which, according to the German weights, given in Mr. Gray's *Elements of Pharmacy*, is the 131,072d part of the weight in each scale; so that this balance was a very good instrument.

The balance used by Mr. Cooper (*Trans. Soc. Arts*, vol. 41), and made by Mr. Robinson, was sensibly affected by 1-400th of a grain, when the scales were loaded with 1000 grains at each end; so that this balance may be esteemed of very great accuracy, and very fit for the purposes to which it was applied; namely, the analysis of organic substances by fire.

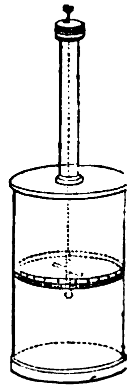
In all researches which depend upon the accurate weighing of the articles employed, and of the products obtained, the accuracy of the balance employed ought ever to be stated, in order that it may be determined what confidence ought to be placed in the results obtained.

The mechanic will, from this account of balances, be able to form a proper estimate of the value to be attached to tables of specific gravity, or to chemical analysis, which depend on a supposed accuracy in weighing which is not attainable in practice. When, indeed, tables of specific gravity are given to five places of figures, the last figure is merely a guess figure; and if they have more than five figures, the author, as Nicholson justly observes, either deceives intentionally, or through ignorance of decimals.

Balance, Electrical; an instrument employed to measure the repulsive and attractive powers of electrified bodies. The nature and operation of this apparatus will be best understood by reference to the accompanying illustration.

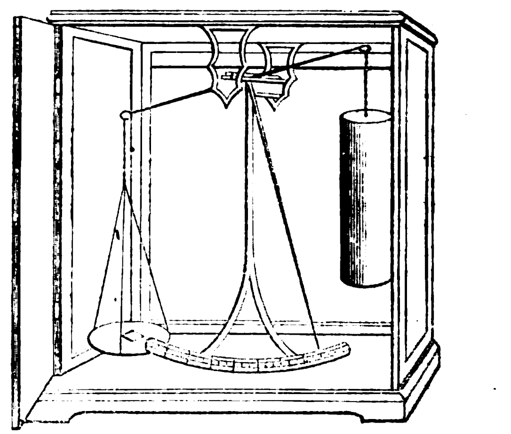


It consists of a large graduated arc, *d*, supported by a projecting plate of brass which is attached to the perpendicular column *k*, the axle of this wheel rests on four small friction wheels, *ff*, and its centre is that of the graduated arc *ab*. Attached to the axle is an index, *c*, formed of an exceedingly fine straw, the motion of which in connection with that of the wheel *d* serves to indicate the amount of revolution of the latter. Over this wheel, and in a groove, at its circumference, passes a line, to the one extremity of which is attached a light ball of gilt wood, *g*, and to the other, a float *il*, which consists of a glass tube about two-tenths of an inch in diameter, terminating in a small bulb, *l*, at its lower end, which contains a small portion of mercury or some very fine shot, put into it for the purpose of adjusting the instrument, so that the index hand, *c*, may point to the *zero* division, or that in the centre of the arc, as exhibited in the engraving. The difference of the weight of this float when in and out of the water is known, and every tenth of an inch of the tube which is immersed or emerged, according as it sinks or rises on the fluid, is made to correspond, by employing a wheel of its required circumference with five divisions of the arc. The body, whose electricity is to be measured, is presented at *h*, and its attractive or repulsive power relative to the ball *g* is estimated by the rising or falling of the float in the fluid, and the consequent motion of the index hand, *c*, over a corresponding portion of the arc *a*. When the attractive force of the two bodies is to be estimated, the line, which passes over the wheel *d* must be formed of two parts, the lower part being of silver thread and the remainder of silk; when their repulsive force is to be estimated, the whole is of silk.



Balance Torsion. This instrument was first suggested by Coulomb, for electrical purposes: it is, however, equally fitted for measuring the intensity of the magnetic force. It consists of a glass cylinder, on which is placed a plate supporting an upright tube. In the centre of the tube is a brass circle and hook, supporting a fine silk thread. Now, we may suppose a small magnet suspended by the line, and all communication with the air cut off by the glass case. On bringing a magnet, whose strength we wish to measure, in contact with the glass, the experimenter will find, by the point of graduation at which it acts on the suspended needle, the exact power of the secondary magnet.

Balance *for the Weather*. This is an instrument which serves to indicate the density of the air, and,



as such, the chances of rain or dry weather. The balance in the above figure has its arms equal, and to one side is attached a large and thin cylinder, exactly balanced by a brass weight in the scale. Now, if we suppose the beam to be in equilibrio when the air is at a given density, and the air become heavier, the equilibrium will be destroyed, as the large cylinder displaces more air than the brass weight, and as such will be more buoyant, and ascend. If, on the contrary, the air become lighter, then it will sink. A rod descending from the scale beam, by passing over the graduated arch, serves to indicate the weight of the air at the time of making the observation. If the air be heavy, then fine weather may be expected; but if the cylinder sink, then rain is the usual result.

Balance, in *Horology*. See Watch-Making.

Balancing; among seamen, the contracting a

sail into a narrower compass, in a storm, by folding up a part of it at one corner, by which it is distinguished from *reefing*. Balancing is peculiar to few sails.

BALCONY, in *Architecture;* a projection from the front of a house, surrounded by a balustrade or open gallery. In common houses these are simple projections, supported by trusses of wood, stone, or iron, and surrounded by a plain or ornamental railing; but they are susceptible of considerable elegance of decoration, and may be supported by columns, caryatides, carved trusses, or cantalivers, and covered by elegant canopies, supported in a similar manner.

BALDACHIN, in *Architecture* and *Sculpture;* a kind of canopy, ornamented with sculpture, and supported by columns for the embellishment of altars; but more particularly used to those which are insulated, like the great altar in the church of St. Peter at Rome.

BALDWIN'S PHOSPHORUS, a phosphorescent substance, formed by calcining nitrate of lime at a low red heat.

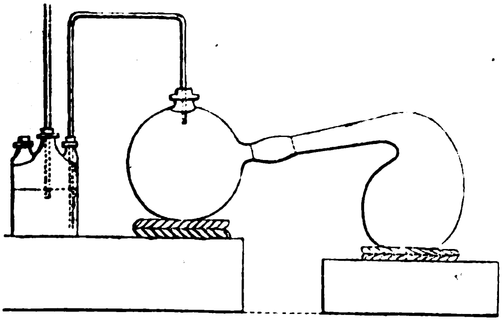
BALISTÆ or BALLISTÆ; a kind of machine for besieging, or attacking the besiegers, in use among the ancients, by which heavy stones, also arrows and other weapons, were thrown; and even burning substances and dead bodies, by the besiegers. Many of the ancient writers confound the *balistæ* with the *catapultæ*, but Polybius makes a difference, using the latter word only for those machines which threw stones. The mechanism of these machines is not quite clear. There is a third name for a kind of these machines—*onager*. The weight of the stones thrown was from 10 to 300 pounds. Sometimes a large quantity of stones was thrown at once. A clear idea of these instruments cannot be formed without the study of treatises on the arms and warfare of the ancients. See ARIES.

BALK, in *Agriculture;* a ridge or bank between two furrows, or pieces of arable land.

BALLIUM, in *Ancient Architecture;* the court within a fortified castle. There were generally two, the outer ballium immediately within the gates, separated by a wall from the inner ballium, which contained the apartments for the garrison and governor. St. Peter in the Bailey, at Oxford, stands in the outer ballium of the castle. The Old Bailey in London is so named for occupying a similar situation.

BALLOON. See AERONAUTICS.

BALLOON, in *Chemistry*. This is a very useful glass implement. Its application is shown in the



wood-cut, in which a retort is seen entering the mouth of the balloon to which it is luted. In this case it serves to condense the vapour which passes from the retort, and thus forms a distillatory apparatus. The non-condensible gases pass up by the bent tube, and then descend beneath the level of the water in a Woulfe's bottle.

BALLAST (from the Danish *baglast*), is a load of sand or stones, deposited in ships, which have not freight enough to sink them to their proper depth in the water, so as to resist the wind and waves. In storms, if the vessel leaks, part of the ballast must often be thrown out, to make the vessel lighter. By the English navigation act, and by the laws of other commercial nations, subsequently established, vessels are often obliged to take ballast, either on their departure or return, instead of transporting, even at little profit, heavy and cheap goods of the country, to foreign states.

Mr. Rewcastle has an ingenious patent mode of preserving the equilibrium of ships, which may here be noticed. The intention of the patentee is to ballast vessels by means of water introduced into the hold of the ship, instead of dry articles. In order to effect this object, he proposes to divide the hold of the vessel into a number of distinct compartments, by placing partitions between the ribs or timbers, which are to be made up by boarding, and the joints carefully caulked, so as to prevent the leakage of water; over the planking, is to be placed sheets of felt, such as are usually prepared for sheathing the bottoms of ships, and upon these may be placed sheets or plates of iron, which being made perfectly tight, will constitute a series of tanks capable of holding water, by which the ship is to be ballasted.

In such ships as are weak in their structure, it may not be desirable to form the compartments or tanks as parts of the vessel itself, it is therefore proposed, in those instances, to construct moveable tanks or boxes of iron, which shall exactly fit those parts of the hold where the ballast is to be placed; and these tanks being filled with water, will answer the same purpose.

The tanks, whether made as compartments in the hold of the ship, or as distinct tanks to be placed in the hold, must be securely covered to prevent the water from flowing over, as the ship rolls or pitches, and pipes must be properly placed, leading to the tanks, for the purpose of conducting the water into these, and other pipes, to discharge it, which pipes must be furnished with stop-cocks; and there must also be tubes in the tops of the tanks, to allow of the ingress and egress of the air.

BALM OF GILEAD is the dried juice of a small tree or shrub (*amyris gileadensis*), which grows in several parts of Abyssinia and Syria. This tree has spreading, crooked branches; small, bright-green leaves, growing in threes; and small, white flowers on separate footstalks. The petals are four in number, and the fruit is a small, egg-shaped berry, containing a smooth nut.—By the inhabitants of Syria and Egypt, this balsam, as appears from the Scriptures, was in great esteem from the highest periods of antiquity. We are informed by Josephus, the Jewish historian, that the balsam of Gilead was one of the trees which was given by the queen of Sheba to king Solomon. The Ishmaelitish merchants, who were the purchasers of Joseph, are said to have been travelling from Gilead, on the eastern side of Canaan, to Egypt, and to have had their camels laden with "spicery, balm and myrrh." It was then, and is

still, considered one of the most valuable medicines that the inhabitants of those countries possess. The virtues, however, which have been ascribed to it exceed all rational bounds of credibility. The mode in which it is obtained is described by Mr. Bruce: The bark of the tree is cut with an axe, at a time when its juices are in their strongest circulation. These, as they ooze through the wound, are received into small earthern bottles; and every day's produce is gathered, and poured into a larger bottle, which is closely corked. When the juice first issues from the wound, it is of a light-yellow colour, and a somewhat turbid appearance; but, as it settles, it becomes clear, has the colour of honey, and appears more fixed and heavy than at first. Its smell, when fresh, is exquisitely fragrant, strongly pungent, not much unlike that of volatile salts; but if the bottle be left uncorked, it soon loses this quality. Its taste is bitter, acrid, aromatic, and astringent. The quantity of balsam yielded by one tree never exceeds 60 drops in a day. Hence its scarcity is such, that the genuine balsam is seldom exported as an article of commerce. Even at Constantinople, the centre of trade for those countries, it cannot, without great difficulty, be procured. In Turkey, it is in high esteem as a medicine, an odoriferous unguent and cosmetic. But its stimulating properties upon the skin are such, that the face of a person unaccustomed to use it becomes red and swollen after its application, and continues so for some days. The Turks also take it in small quantities, in water, to fortify the stomach, and excite the animal faculties.

Balsam. The term *balsam* was formerly applied to any strong-scented, natural, vegetable resin, of about the fluidity of treacle, inflammable, not miscible with water without addition, and supposed to be possessed of many medical virtues. All the turpentines, the Peruvian balsam, copaiba, &c., are examples of natural balsams. Many medicines, also, compounded of various resins or oils, have obtained the name of *balsams;* as Locatelli balsam, &c. Lately, the term has been restricted to those resins which contain benzoic acid. The most important balsams are those of Tolu and Peru—*storax* and *benzoin*, as they are named: the latter is concrete, the former fluid, though becoming solid with age. They are odorous and pungent, and useful only as articles of the materia medica. The benzoic acid is extracted from them by applying a gentle heat, when it is volatilized and afterwards condensed.

Baluster, in *Architecture;* a small turned column usually introduced between piers, on the upper parts of large buildings under windows, and on balconies, &c.

Balustrade, in *Architecture;* a row of balusters.

Bangue; a kind of opiate, much used throughout the East as a means of intoxication. The Persians call it *beng*. It is made of the leaf of a kind of wild hemp, in different ways.

Banner; a word found in all the modern languages of western Europe, the origin of which, however, is given in many very different ways. It signifies the colours, or standard. Among the ancient Germans, if a knight was able to lead 10 helmets, that is to say, 10 other knights, against the enemy, the duke (*herzog*) gave him a banner, and he was called a baneret (*bannerherr*). In some republics, banneret, or standard-bearer, was the title of one of the highest officers, as the *gonfalionere* of Florence and other Italian republics, and the *bannerherr* in the Swiss republics. Banneret, in England, was a knight made in the field, with the ceremony of cutting off the point of his standard, and making it a banner—a custom which has long since ceased. Several banners are famous in history, as the Danish banner, taken from the Danes by Alfred the Great, the *oriflamme*, &c. Catholic churches generally have their banners.

Banquette, in *Fortification;* the elevation of earth behind a parapet, on which the garrison of a fortress may stand, on the approach of an enemy, in order to fire upon them. The height of the parapet above the banquettee (the height of defence), is usually about four feet six inches; the breadth of the banquette, when it is occupied by one rank, two and a half to three feet; when it is occupied by two ranks, four to six feet. It is frequently made double, that is, a second is made still lower.

Barbette; an elevation of earth behind the breastwork of a fortification or intrenchment, from which the artillery may be fired over the parapet. The height of the breasting (the part of the parapet which covers the cannon) is generally 3½ feet; the length of the barbette, 14 to 16 feet; the breadth for every cannon, 16 to 18 feet. An ascent leads from the interior of the intrenchment to the barbette. When the garrison has much heavy ordnance, or the enemy has opened his trenches, or when it is determined to cannonade the intrenchments of a given point, as, for example, a bridge or pass, and the direction of the cannon is not to be materially changed, it is usual, instead of making a barbette, to cut embrasures in the parapet: on the contrary, firing from the barbette is expedient when the soldiery expects to be attacked only by infantry, or wishes to cannonade the whole surrounding country.

Barilla; the term applied, in commerce, to a product obtained from the combustion of certain marine vegetables. This word is the Spanish name of a plant (*salsola soda*), from the ashes of which is produced the above substance, which affords the alkali (soda). This is also procured from the ashes of prickly saltwort, shrubby saltwort (*salsola frutiosa*), and numerous plants of other tribes. The plants made use of for burning differ in different countries; and the residue of their incineration contains the soda in various states of purity. The barilla derived from the *abesembryanthemum nodiflorum* of Spain, and the *M. copticum* of Africa, contains from 25 to 40 per cent. of carbonate of soda; whereas that from the *salsola* and the *salicornia* of other districts affords about half this quantity; and the particular variety known under the name of *kelp*, procured by burning various sea weeds, is a still coarser article, not yielding above 2 or 3 per cent. of real soda. To obtain the carbonate of soda, it is only requisite to lixiviate the barilla in boiling water, and evaporate the solution.—On the shores of the Mediterranean, where the preparation of soda is pursued to a considerable extent, the seeds of the plants from which it is obtained are regularly sown in places near the sea. These, when at a sufficient state of maturity, are pulled up by the roots, dried, and afterwards tied in bundles to be burnt. This, in some places, is done in ovens constructed for the purpose, and, in others, in trenches dug near the sea. The ashes, whilst they are hot, are continually stirred with long poles, and the saline matter they contain forms, when cold, a solid mass, almost as

hard as stone. This is afterwards broken into pieces of convenient size for exportation. The best sort of Spanish soda is in dark-coloured masses of a bluish tinge, very heavy, sonorous, dry to the touch, and externally abounding in small cavities. Its taste is very sharp, corrosive, and strongly saline. The important uses of soda in the arts, and especially the constant consumption of it in the manufacture of all kinds of fine and hard soaps, are well known. The greater part of the barillas or crude sodas of commerce are now obtained from the ashes of various sea weeds, which manufacture is extensively prosecuted upon the extensive shores of Scotland.

A new mode of preparing barilla must now be noticed, it is the patent invention of Mr. M'Leod. We cannot do better than quote his specification, as it gives a concise view of the process, and the circumstances which led to the discovery.

"Travelling along the coast of Coromandel, at certain seasons of the year, the ground in many places is observed to be covered with a white efflorescence, which on examination will be found to consist chiefly of muriate and sesqui-carbonate of soda. These substances are collected by the natives, and used by them for a variety of purposes.

"The ground on which this efflorescence appears, is never covered with verdure. The soil is a deep sand with a mixture of clay, carbonate of lime, &c. The clay contains, as it generally does, some oxide of iron, of which whole fields on the west side of the great Pulicate Lake, forty or fifty miles north of Madras, are of this description.

"Carbonate of soda is met with only on the surface, and it is found in greatest abundance a few weeks after the periodical rains have ceased. The natives begin collecting it in March, and continue to do so during the hot weather that succeeds. The saline crust is scraped from the surface, mixed with sand and clay, washed in water so as to separate some of the insoluble matter, and the watery solution is evaporated to dryness. The residuum thus obtained, is the karum of the bazars, and is the only preparation hitherto made or used in India of these materials.

"This karum contains from four to six or eight per cent. of soda, and the rest consists of carbonic acid, sand, clay, muriate of soda, decomposed vegetable matter, and occasionally other impurities. Various attempts have been made to introduce this substance into our manufactories, and with this view consignments of it have at different times been sent from Madras, but the nature and quantity of its impurities effectually excluded it.

"Some years ago it occurred to me, that if it were divested of some of its insoluble matter, and submitted to the action of fire so as to free it from a portion of carbonic acid, decomposed vegetable matter, water, sulphur, and other volatizable impurities, it might become an article of considerable importance. I conceived that if the karum were treated in this manner, and fused in a reverberatory or other furnace, it might be converted into a substance resembling barilla, which would be found a perfect substitute for that article. This idea I soon after put in practice, but my first attempts were unsuccessful.

"The materials above mentioned being fused in a reverberatory furnace, became a mass of green glass, in consequence of their containing a quantity of silecious matter, of which they had not been sufficiently divested. It therefore became necessary to get rid of this admixture by more careful solution and evaporation to dryness, as already mentioned. These operations being performed with sufficient care, the residuum underwent the action of fire without any sensible portion being converted into glass, and the fused mass being withdrawn and cooled, resembled very fine barilla in most of its essential properties; and in fact passes current in the London and Antwerp markets as barilla of a superior quality."

Bark, Peruvian, is the produce of various species of the *cinchona*, which is the spontaneous growth of many parts of South America, but more particularly of Peru. The tree is said somewhat to resemble a cherry-tree in appearance, and bears clusters of red flowers.—This valuable medicine was formerly called *Jesuit's bark*, from having been introduced into Europe by the members of that religious order, who were settled in South America. They were instructed in the use of it by the natives of Peru, to whom it had been long known; and it continued, for many years, a source of profit to the order. Its botanical name was derived from that of the Countess del Cinchon, the lady of a Spanish viceroy, who had been cured by it. The tree from which it is obtained grows abundantly in the forests of Quito and Peru, and the bark is cut by the natives in the months of September, October, and November, during which alone, the weather is free from rain. The bark is of three kinds—the red, the yellow, and the pale. The first has now become scarce, but has also lost the exclusive reputation which it once had, the yellow and pale barks having been found to be stronger in their febrifuge properties. The *crown-bark*, as the highest priced is termed, is of a pale, yellowish-red. The uses of the bark in medicine are too well known to need description; but the chemical discoveries in relation to it are deserving of more particular mention. Its medical properties were found, a few years since, to depend upon the presence of a substance called *quinine*. This exists, more or less, in all kinds of Peruvian bark, but in quantities very unequal in the various kinds. It was discovered by Messrs. Pelletier and Cavatou, who also ascertained that the most useful and permanent form of the substance was that of a neutral salt, in which it was combined with sulphuric acid, constituting the celebrated sulphate of quinine. This extract is so powerful, that one grain of it is a dose; and thus does this little powder, which is almost imperceptible, supply the place of the nauseous mouthsful of bark, which were absolutely eaten by the unfortunate beings who were afflicted with the ague, before this invaluable article was discovered. Next to the bleaching liquor and the gas-lights, this may be regarded as the most valuable of the gifts of chemistry to her sister arts. So extensive has the manufacture of this most important article become, that, in 1826, no less than 1593 cwt. of bark were used by four chemists concerned in the production of it in Paris; and 90,000 ounces of sulphate of quinine were produced in France in the same year, being enough for the curing, at a fair calculation, of near 2,000,000 of sick, who have by this most happy discovery, been spared the swallowing of at least 10,000,000 ounces of crude bark. This one discovery should entitle the name of Pelletier to the gratitude of all posterity. It may be added as a curious fact in pharmaceutical chemistry,

that the same genius which enabled our Gallic neighbours to extract this important principle from a coarse and woody fibre, has not yet taught them the most convenient mode of preparing it as a medicine. On the Continent it is usually taken in the form of a powder, and the Editor of this work, on asking for the sulphate of quinine prepared as pills, has repeatedly been recommended to take the white and bitter powder between bread and butter. In this country it is usually taken in the form of a pill, or in the infusion of rose leaves.

Barometer. There is no philosophical instrument so much consulted as the one we are now about to describe. Strictly speaking, it can rarely be considered as a perfect index to the ever-varying density of our atmosphere, but there is no other contrivance which science has furnished equally calculated for foretelling changes in the weather. It would be a waste of our reader's time to go much into the history of the barometer, and it may be enough to state that Torricelli discovered the principle on which it acts, but Pascal applied that principle to useful purposes in the construction of what is properly called the weather-glass.

It has been shown in the articles Air and Atmosphere, that the invisible fluid which surrounds us, is material,—possesses weight, and as such, must press on all bodies which are immersed in it. Now, if by a very simple process, which will shortly be described, we remove the weight of the air from within a tube, and fill the tube with mercury, the fluid will remain suspended, and in a state of equilibrium, when the column of mercury is an exact balance to the air's pressure. Now this is exactly the arrangement adopted in constructing the barometer.

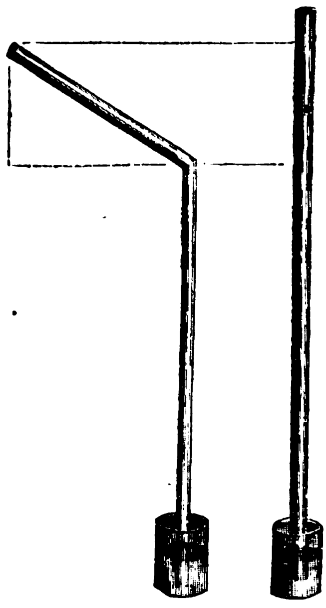
The glass tubes of which barometers are made, should have a bore of not less than one-third of an inch in diameter, and they should be perfectly clean within. To prevent their contracting any impurity before they are used, it is usual to hermetically seal both their ends at the glass-house. Being provided with a tube of this description, on preparing it for a barometer, one of its ends must be removed with a file.

Mercury in a state of great purity, is very essential to a good barometer. It is generally purified by distillation, but as this operation may not be convenient to some, we shall mention Dr. Priestley's mode of purifying it, which is remarkable for its simplicity, and has an excellent effect:—Let a strong 10 or 12 ounce phial, with a ground stopper, be a quarter filled with the mercury to be purified; put in the stopper, hold the bottle inverted with both hands, and shake it violently, by striking the hand that supports it against the knee. After twenty or thirty strokes, take out the stopper, and blow into the phial with a pair of bellows, to change the air. If the mercury is not pure, the surface will become black in a short time, and if very foul, a black coat will coagulate on the surface. Invert the phial, stopping it with the finger, and let out the running mercury. Put the coagulated part into a cup by itself, and press it repeatedly with the finger so as to get out the mercury entangled in it. Put both portions of mercury into the phial again, and repeat the process till no more black powder separates.

After the mercury has been thus purified from its admixture with baser metals, it should be boiled for about half an hour, to free it from the moisture which it is apt to contain. It may then, when nearly cool, be poured into the tube till it reaches to within two inches of the top; then to free it from the air, hold it with the sealed end lowest, in an inclined position over a chafing-dish, placed near the edge of a table, in order that all parts of the tube may be exposed successively to the action of the fire, by moving it obliquely over the chafing-dish. The sealed end is to be first gradually presented to the fire, and the other parts in slow succession. The air, if any be contained in the tube along with the mercury, will by this means be expanded, and rising to the top of the tube, will escape. The tube must now be filled to the brim, the open end stopped with the finger, and plunged into a bason of mercury. The finger must then be taken away, and the tube being held vertically, the mercury in it will remain suspended at the height of about 29 or 30 inches, or indeed, whatever balances the pressure of the atmosphere at the time.

The accompanying engraving exhibits an arrangement for removing the air from the mercury, by the agency of a pump. The lower disk represents the pump-plate, on which is placed a glass receiver. The barometer tube is kept air tight by a collar of leathers, and the lower extremity dips into a cup of mercury. Now it will be obvious that as soon as the pump is worked, and the receiver exhausted, if we readmit the air, the mercury will be driven up purified of the air which otherwise adheres in considerable quantities.

It may be proper to add, that even in the most perfect barometer, an atmosphere of mercury occupies the upper part of the tube, and independent of that defect, air is usually found to pass down the external surface, and thus destroy the perfection of the vacuum.



A barometer constructed on the principles we have now been describing, but in the simplest form, is shown in the engraving, and beside it is placed another, which possesses some advantages over that instrument. The straight tube is supposed to be of the ordinary length, and possessing a range of three or four inches; the bent tube, on the contrary, offers a range of nearly double that amount. It is called the *angular* barometer, and the only defect which is found in this form arises from the increased friction of the mercury in the tube.

The mercury in the barometer is seldom to be seen so low as 28 inches, or higher than 30½. It indicates as follows:—

31 inches . . . Very dry weather, hard frost.
30½ . . . . . . Settled fair, settled frost.
30 . . . . Fair, frost.
29½ . . . . . . Changeable.
29 . . . . Rain, snow.
28½ . . . . . . Much rain, much snow.
28 . . . . Stormy weather.

In January, 1822, the mercury fell to 28, which is said to have been the lowest ever remarked in England. By the fall, a pressure equal to 2,000lbs. was removed from each person's body, yet probably no individual was at the time conscious of it. The maximum height of the mercurial column is about nine o'clock A. M.; the mean at twelve, and the minimum at three P. M. If the column rise from nine A. M. to three P. M. it indicates fine weather; if it fall during that interval, rain may be expected.

We have now to call the reader's attention to a series of observations by Mr. Walker, a knowledge of which will materially facilitate our acquaintance with the instrument, and its uses.

1. The barometer rising, may be considered as a general indication that the weather, comparatively with the state of it at the time of observation, is becoming clearer.

2. The atmosphere apparently becoming clearer and the barometer above *rain*, and rising, show a disposition in the air for fair weather.

3. The atmosphere becoming clear, and the barometer above *changeable*, and rising, indicate fair weather.

4. The atmosphere clear, and the barometer near *fair*, and rising, denote continued fair weather.

5. Our prognostic of the weather is to be guided relatively, thus: if notwithstanding the sinking of the barometer, little or no rain follow, and it afterwards rise, we may expect continued dry weather.

6. If, during a series of cloudy rainy weather, the barometer rise gradually, though yet below rain, especially if the wind change from the south or west towards the north or east points, clear and dry weather may be expected.

7. The weather for a short period, viz. from morning until evening, may commonly be foretold with a considerable degree of certainty. If the barometer has risen during the night, and is still rising, the clouds are high and apparently dispersing, and the wind calm, especially if it be in or about the north or east points, a dry day may be confidently expected. The same rule applies for predicting the weather from evening till morning.

8. During the increase of the moon there seems to be a greater disposition or effort in the air for clear dry weather, than in the wane; but this disposition does not usually commence till about three or four days after the new moon, and ceases about three or four days after the full moon.

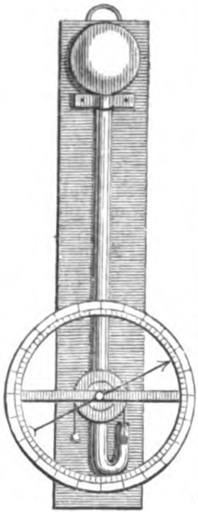
9. The barometer should be observed occasionally thrice in the day, or oftener when the weather is changeable, in order to notice whether the mercury be stationary, rising, or sinking; for, from this circumstance, together with the direction of the wind and the apparent state of the air at the time, is information to be collected; and a continuance of the same, or a sudden change of the weather, to be foreseen.

Lastly, observe always, the higher the mercury shall stand in the scale in each instance, and the more regularly progressive its motion shall be, the stronger will be the indication: likewise, the more the wind inclines towards the north or east points, the greater will be the disposition in the air for fair weather. The indications of rainy weather will obviously be the direct reverse of those rules which predict fair weather. Frost is indicated in winter by the same rules that indicate fair weather; the wind being in or about the north or east points, and the thermometer sinking towards 30. A fall of snow seldom comes without a previous frost of some duration, and is indicated by the sinking of the barometer; especially if the mercury be below *changeable*, and the thermometer at or near the freezing point. When the temperature of the air is about 35, snow and rain sometimes fall together; at a warmer temperature than 35 it seldom snows, or rains at a colder temperature. Thunder is presaged by the same rules which indicate rain, accompanied by sultry heat; the thermometer being up to 75. Storms, hurricanes, and high winds, are indicated by the barometer falling suddenly, or sinking considerably below *much rain*. The barometer is known to be rising or sinking, by the mercury having either a convex or concave surface; or by the perceptible rise or descent of the mercury, if at the time of observation the barometer be gently rapped. If at any time the weather should differ widely from the indications of the barometer, it may be presumed, as it is sometimes known to happen, that a particular spot is affected by local circumstances. After a long-continued series of wet weather, we may, when the weather becomes fine, expect an uninterrupted continuance of dry weather. If, after a long series of wet weather, the barometer rise above *changeable*, and the wind veer steady to the north or east points, a continued duration of fair weather may be expected. Slow and progressive variations in the barometer, with a fixed and steady state of the wind, indicate permanency with the change. The barometer standing at or above *fair*, denotes generally fair weather, although the atmosphere wear at the time an unfavourable aspect.

The greater coincidence there is of the circumstances enumerated in the rules above mentioned, the stronger may our confidence be in the expectation of fair weather; and in the continuance of it when present, by the barometer whilst high remaining stationary, or varying but little, and the state of the atmosphere and direction of the wind disposed to be settled. In this variable climate there is no reliance to be placed on any rules beyond those above mentioned, for indicating the weather for any length of time together, or for any distant period.

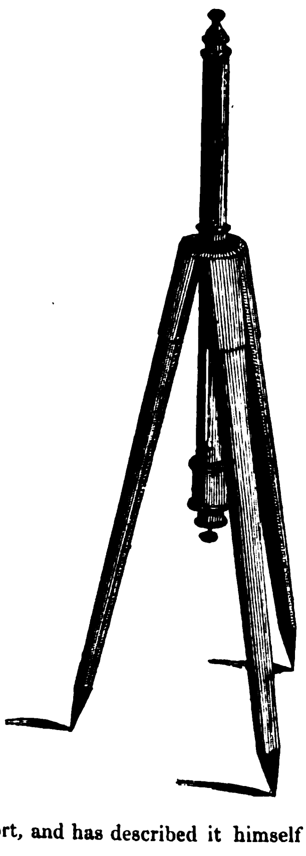
The straight tube we have already described, though it does not possess the largest range, is assuredly the most perfect form of the instrument. The *wheel barometer* is even less perfect than the diagonal one, and yet as that is the ordinary form of the weather-glass, its arrangement should be illustrated. Before doing which, it may, however, be proper to guard our readers against the purchase of instruments of this description, sold by foreign vendors about the streets of the metropolis. They are usually made in the most imperfect manner, and the mercury with which the tube is filled, adulterated with lead, which gradually discolours the glass and destroys the value of the barometer.

The accompanying engraving represents a glass tube containing mercury, having a large round head or ball, and bent upwards at the bottom. Upon the surface of the mercury in the curved leg, is placed a short glass float, loaded with the same material, with a string passing over a pulley, and balanced by another weight hanging freely in the air. As the surface of the mercury in the ball is very large, and that at the bottom of the tube comparatively small, the motion of the quicksilver, and consequently of the balance or float at bottom, will be very considerable: but as the weight moves up and down, it turns the pulley, and to that is attached a hand, or index, which passes over the divisions of a large graduated circle.



The common *portable barometer* has a small bag, for the purpose of containing the mercury, so that no part of it is exposed to the atmosphere; but the air presses upon the outside of the bag. To render the instrument perfectly portable in its frame, a screw, is used to force the mercury to the top of the tube.

Portable barometers, such as are shown in the accompanying engraving, are chiefly required for measuring the heights of mountains, and they should always be constructed in the most accurate manner. The mercury in the cistern must be raised always to the same mark or distance from the scale, in order that the divisions of the scale may indicate the real altitude of the surface of the mercury in the tube above that of the mercury in the cistern. They should also be furnished with a triangular stand, capable of supporting them in exactly a vertical position, as shown in the figure. Mr. Ramsden, an eminent philosophical instrument maker, contrived a valuable barometer of this sort, and has described it himself in the *Philosophical Transactions*. The principal parts of it are a simple straight tube, fixed into a wooden cistern, which, for the convenience of carriage, is closed with an ivory screw, and, that being removed, is open when in use. From this aperture is distinctly seen the coincidence of the gauge-mark, with a line on the rod of an ivory float swimming on the surface of the fluid metal, which is raised or depressed by a brass screw at the bottom of the cistern. From this, as a fixed point, the height of the column is readily measured on the scale attached to the frame. The thermometer is placed near the cistern. the ball of which is not inclosed within the woodwork, but left projecting. The three-legged stand, supporting the instrument when in use, serves as a case for it when inverted, and carried from place to place. Two of these barometers, made by the inventor, after the mercury in them had been carefully boiled, being suffered to remain long enough in the same situation to acquire the same temperature. usually agreed in height, or rarely differed from each other more than a few thousandth parts of an inch.



When the barometer is used for measuring the heights of mountains, or other elevations, the temperature of the mercury must be considered, as well as its elevation; because it will expand and contract with heat and cold, and the upper regions of the atmosphere are much colder than those below. The general principle of these kinds of measurement may be understood from the following illustration:—When the barometer on the surface of the earth stands at 30 inches, and the temperature is 32 Fah., it has been ascertained by trial, that taking such barometer to the perpendicular height of 87 feet, lowers the mercury about one-tenth of an inch, or will cause it to fall to 29.9; but presuming it to be raised still higher in the air, or until it descends another tenth of an inch, or stands at 29.8, it is required to know how much it has been elevated? The second stratum of air is evidently equal in weight to the first, because each has produced an equal depression of the mercury: but since, from the nature of the atmosphere, each succeeding stratum is lighter or less dense as we ascend, so the second stratum, to be of equal weight, must be of greater height than the first, and consequently the whole ascent must be more than twice 87 feet. To examine this difference, the density of the first stratum of air may be represented by the number of tenths of an inch of mercury which it is capable of supporting; and as the column was supposed to be at 30 inches high, this will be 300: for the same reason, the density of the second stratum will be represented by 299; but the weights of these two strata are equal, therefore their bulks must be inversely as their densities; and since their bases are equal, difference of bulk can only arise from difference of height; and, consequently, to obtain the thickness of the second stratum of air, or its height above the first, it will only be necessary to say 299 is to 300, as 87 feet, the height of the first stratum, is to 87.29 feet, which will be the height of the second; so that the whole distance ascended will be 174.29 feet. In like manner, if the barometer is carried upwards until the mercury falls to 29.8, then the proportion will be 298 : 300 :: 87 feet, : 87.584; or it will have ascended to the height of 261 feet and 7-8ths.

Baron; a word derived from the Latin, which signifies a *man*, but, sometimes, a *servant*. In the feudal

system of the middle ages, at first, the immediate tenant of any superior was called his *baron*. In old records, the citizens of London are so styled, and the 16 members of the house of commons, elected by the cinque-ports, are still called *barons*. The family of Montmorency called themselves, in France, *premiers barons de la chrétienté*. This name was introduced by William the Conqueror from Normandy to England, and used to signify an immediate vassal of the crown, who had a seat and vote in the royal court and tribunals, and, subsequently, in the house of peers. It was the second rank of nobility, until dukes and marquises were introduced, and placed above the earls, and viscounts also set above the barons. In Germany, the ancient barons of the empire were the immediate vassals of the crown. They appeared in the imperial court and diet, and belonged to the high nobility. But these ancient feudatories were early elevated to the rank of counts or princes. The modern barons only form a rank of lower nobility after the counts.—*Barons of the Exchequer;* four judges in England and five in Scotland, to whom the administration of justice is committed, in causes between the king and his subjects, relating to the revenue. They were formerly *barons of the realm*, but, of late, are, generally, persons learned in the laws.

BARONETS; a hereditary dignity in Great Britain and Ireland, next in rank to the peerage, originally instituted by James I., May 22, 1661. It is said that Lord Chancellor Bacon suggested the idea, and the first baronet was Sir Nicholas Bacon of Redgrave. Baronets are created by patent, under the great seal, and the honour is generally given to the grantee and the heirs male of his body lawfully begotten, though sometimes it is entailed on collaterals. From the preamble of the original patent, it appears that the order was created to get money for the support of soldiers in Ireland, each baronet, on his creation being obliged to pay into the treasury a sum little less than 1100*l*. In 1823, there were 661 baronets in England. Precedency is given to baronets before all knights, except those of the Garter, bannerets created on the field, and privy counsellors.

Baronets of Ireland; an order instituted by James I., for the same purpose, and with the same privileges, as the baronets of England. Since the Union, in 1801, none have been created otherwise than as baronets of the United Kingdom. A hereditary dignity, somewhat similar to knighthood, appears to have been conferred, in this country, even in very ancient times.

Baronets of Nova Scotia, and Baronets of Scotland. Charles I. instituted this order in 1621, for the purpose of advancing the plantation of Nova Scotia, in which the king granted a certain portion of land to each member of the order. Since the union, the power of the king to create new baronets within Scotland is held to have ceased.

BARRICADE, or BARRICADO; those objects which are hastily collected, to defend a narrow passage (for instance, the street of a village, a defile, a bridge, &c.), the moving of which retards the enemy, and gives to the sharp-shooters, posted behind or in its neighbourhood, an opportunity of firing upon them with effect. Waggons, harrows, casks, chests, branches of trees, beams,—in short, every thing which is at hand, is used for this purpose; and, if it is necessary that the enemy, when consisting principally of cavalry, should be checked in the pursuit, though it be but for a moment, the ammunition and baggage-waggons may be employed with effect.

Some of the most remarkable instances of the use of the barricade on record, are those which occurred during the late revolution which placed Louis Philip on the throne of France.

BARYTES; the name of one of the earths. It is procured either from the native sulphate of barytes, by exposing its powder to a red heat with charcoal, and by forming from the resulting sulphurate a nitrate, which is decomposed by heat; or from the native carbonate, by dissolving it in nitric acid, and, in like manner, subjecting it to the heat. Thus obtained, barytes has a specific gravity of 4, is of a gray colour, has a caustic taste, and slakes on exposure to the air, like lime falling to powder from the absorption of water. It is soluble in 25 parts at 60°, and in the proportion of nearly half its weight at 212°. The solution, on cooling, affords prismatic crystals. Its watery solution possesses, distinctly, alkaline properties, changing the vegetable blues to green, and acquiring a film upon its surface, when exposed to the air, from the absorption of carbonic acid. It operates as a virulent poison when taken into the stomach. To the flame of alcohol it imparts a yellow colour, which, together with its great solubility in water, serves to distinguish it from the other earths. It is useful in chemical analysis, in consequence of its property of uniting by fusion with several of the earths and metallic oxides, and rendering them soluble in acids or water.—Barytes has been decomposed by the agency of galvanism, and ascertained to be the oxide of a peculiar metal, to which Sir Humphrey Davy has given the name of *barium*. It has a white colour, with a metallic lustre, resembling that of silver. Exposed to the air, or thrown into water, it absorbs oxygen, and is converted into barytes.—Barytes combines with the acids, and forms a variety of salts, two of which, the carbonate and the sulphate, are found abundantly in nature. The first of these is called, in mineralogy, *Witherite*, from Dr. Withering, its discoverer. It is commonly fibrous or bladed in its structure, occasionally including small cavities lined with minute crystals. It is whitish, translucent, and glistening. Specific gravity, 4.3. It is composed of barytes, 78, and carbonic acid, 22. Like all the other salts of barytes (with one exception), the carbonate is a virulent poison, and has often proved fatal to domestic fowls and animals who have accidently swallowed it, about the mines where it occurs. Its principal localities are in the north of England, where it is found in lead mines: it also occurs in Stiria, Salzburg, and Siberia. It is used to obtain the pure barytes, and those salts of this earth which are employed as chemical tests, and for the purposes of scientific illustration.—The sulphate of barytes, called, in mineralogy, *heavy-spar*, is found abundantly in almost every country, usually accompanying galena, or common lead ore, of which it frequently forms a part. It is often beautifully crystallized under a variety of forms, derived from a right rhombic prism of 101° 42′, and 78° 18′, but is more generally, lamellar or compact. It presents numerous colours, of which white is the most frequent. It is translucent, and sometimes transparent, capable of being scratched by the knife, and of a specific gravity of 4.7. Like the artificial sulphate of barytes, it is insoluble, and is the only salt of this earth which is not poisonous. It consists of 67 parts barytes and 33 sulphuric acid. It is em-

ployed, though less extensively, for the same purposes as the carbonate, and was formerly used, by Mr. Wedgewood, in the manufacture of his beautiful jasper ware.—A fibrous variety of heavy-spar, called *Bolognian stone*, and which occurs, imbedded in small nodular masses, in a marl near Bologna, has the remarkable property of becoming phosphorescent by calcination.—The *artificial* sulphate of barytes, formed by adding sulphuric acid to the carbonate of barytes, is employed for the purpose of painting in water-colours, and is the most beautiful white now in use. It is known by the name of *permanent white*. The same substance is much valued for marking bottles in chemical laboratories, where the acid vapours destroy common ink, and for labelling articles kept in cellars and moist places. In order to be applied, it is mixed up with spirits of turpentine and linseed oil, to the consistence of common paint, when it is laid on with a brush. If a black marking material is preferred, this may be rendered so by the addition of a little lamp-black.—The *nitrate of barytes* is formed by dissolving the native carbonate in diluted nitric acid, and crystallizes on evaporation. It is soluble in 10 or 12 parts of water, at 60°, and in 3 or 4 parts at 212°.—The *muriate of barytes*, in like manner, is produced by submitting the carbonate to the action of dilute muriatic acid. It is much more soluble than the nitrate. Solutions of both these salts are of great importance in analytical processes, for the detection of sulphuric acid; the barytes forming, with that acid, an insoluble precipitate, while the nitric or muriatic acid neutralizes the base. The muriate of barytes is employed with advantage, as a medicine, in the treatment of scrofulous diseases, though, from its poisonous nature, great caution is requisite in its administration.

Base, in *Architecture* and *Sculpture* ; the foot, or bottom of any figure. The word base is used, generally, for any body which bears another, but particularly for that portion of the lower part of a column, which is between the shaft and pedestal (when a pedestal is used), and differs in the various orders and species of architecture. In Egyptian architecture the bases of columns are mostly simple plinths; and although Dr. Pococke exhibits the base of a column found in Egypt with several tori, yet this circumstance indicates the style to be of the time of Greek architecture prevailing in Egypt. The base of the Tuscan column consists of a torus and fillet; the Doric has none, except a plain plinth, on which it is sometimes elevated, but it is generally placed on a continued plinth or upper step of the temple, as in the temples at Thoricus, Corinth, Agrigentum, Pæstum, Athens, Sunium, and Ægina. Although, in modern times, the attic base has been given to the Roman spoliation of the Doric, yet in the best time of Roman architecture (according to Vitruvius), the Doric was used, as by its inventors, without the base. The Ionic column, in the earliest specimens, has a base, of which the height was half its diameter, and composed of a variety of members. The bases to the Corinthian and Composite orders emanate from the Attic; a torus or two more, a greater number of fillets or beads, two scotiæ, &c., are the general characteristics of these bases. Different bases have been invented, and used both by Greek as well as Roman architects for the Ionic order, but all fall short of the purity of style which characterises the Attic.

Base, or Basis ; a term in tactics, first introduced into military language by Henry von Bülow, who laboured to reduce war to mathematical principles, and to give more certain rules to the commander. By *basis*, he understands a tract of country well protected by fortresses, and from which the operations of the army proceed. The line upon which these operations are executed he calls the *line of operation;* the fortresses from which the operations begin, the *subject;* the point to be first carried, the *object*. Thus, in an offensive war of France against the south of Germany, supposing Prussia and Switzerland to be neutral, the Rhine, from Basle to Carlsruhe, would be the basis ; Strasburg, the subject ; Ulm or Ratisbon, the object; and the road from Strasburg to these places the line of operation. As Bülow thought magazines indispensible, the security of the line of operation against all attacks from the side seemed to him likewise indispensible, and he laid down the principle, that both the lines, drawn from the ends of the basis to the object, ought to meet there in a right or an obtuse angle, the last being preferable. The novelty and importance of the subject, and the severity with which Bülow criticised his opponents, gave rise to a violent dispute. In 1814, the subject was discussed in *Fragmente aus den Grundsäzen der Strategie, erläutert durch die Darstellung des Feldzugs in Deutschland*, 1796 ; a most valuable work, composed by the archduke Charles of Austria. He adopts many of the ideas of Bülow, and rejects others; and, on the whole, establishes the theory of the basis on such grounds, that every unprejudiced military man will be disposed to admit it. He also maintains, that the basis (according to his definition, a straight line, which unites several points at which the stores of the army are collected(must be covered. It ought, since the operation on one road would be dangerous, to include, if possible, several fortified places, connected by easy communications, and to run parallel with the basis of the enemy. If the troops have moved too far from the basis, a new one should be formed. The Archduke explains his principles on a supposed theatre of war in the south of Germany, and by the war which actually took place in that country in 1796, in which he distinguished himself so much. The last wars in Europe have shown the correctness of this theory, which has been acted on, more or less by generals in all ages, and the neglect of which has generally been attended with suffering and defeat. Thus the Prussians, in 1792, advanced, without paying regard to the fortresses of Metz, Thionville, Landau, &c., on one line of operation, and were nearly destroyed at Valmy ; and, for the same reason, the army of Jourdan, in 1796, was almost entirely ruined, after some unfortunate engagements. So the army of Napoleon perished in Russia, because he had not formed, before advancing to Moscow, a new basis on the Dnieper. The war in Spain, also, westward of Madrid, consisted only of detached movements of large columns, which were ineffectual, on account of the want of a proper communication. The allies also were enabled to march from all sides against Napoleon, at Leipsic, in consequence of his having neglected to form a basis at Dresden ; and they themselves were several times exposed to the greatest danger in France, from a similar neglect, when nothing but the boldness of Blücher, and the courage of our troops saved them. It may be objected, that Napoleon owed his greatest glory to campaigns in which he entirely disregarded

the basis; as those of 1806 and 1809, against Austria, and his previous campaigns in Italy; but one single great and decisive battle lost would have punished severely his neglect of this principle. And moreover, there is one rule still more important than those of tactics—to act according to the circumstances and character of the enemy, and to bring on decisive results by energetic measures, rather than to moulder away in inaction. We may remark, also, that the conquest of the capital of a large state is always a most important object, and should be aimed at as speedily as the rules of tactics will allow.

Bass; the lowest part in the harmony of a musical composition. It is the most important of all the parts, the foundation of the harmony, and the support of the whole composition.—*Figured bass* is a bass which, while a certain chord or harmony is continued by the parts above, moves in notes of the same harmony. For example, if the upper parts consist of C, E, G (the common chord or harmony of C), and while they are continued, the bass moves from C, the fundamental note of that harmony, to E, another note of the same harmony, that bass is called a *figured* bass.—*Fundamental bass* is that bass which forms the tone or natural foundation of the harmony, and from which that harmony is derived. To explain this by an example:—if the harmony consist of the common chord of C, C will be its fundamental bass, because from that note the harmony is deduced; and if, while that harmony is continued, the bass be changed to any other note, it ceases to be fundamental, because it is no longer the note from which that harmony results, and is calculated.—*Ground bass* is bass which starts with some subject of its own, and continues to be repeated throughout the movement, while the upper part or parts pursue a separate air, and supply the harmony. This kind of bass was greatly in fashion half a century ago, but has long since been rejected as an unnatural restraint upon the imagination, and productive of a monotonous melody.—*Bass clef* is the character put at the beginning of the stave, in which the bass, or lower notes of the composition, are placed, and serving to determine the pitch and names of those notes.—*Basso concertante* (Ital.) is the bass of the litle chorus; the bass which accompanies the softer parts of a composition, as well as those which employ the whole power of the band. This part is generally taken by the violoncellos.—*Bass-counter* or *contra-bass*; the under bass; that part which, when there are two basses in a composition, is performed by the double basses, the violoncellos taking the upper bass or *basso concertante*.—*Basso recitante* (Ital.); the bass of the little chorus; the same with *Basso concertante*. *Basso repieno* (Ital.); the bass of the grand chorus; that bass which joins in the full parts of the composition, and, by its depth of tone and energy of stroke, affords a powerful contrast to the lighter and softer passages or movements.

Bas-Relief. See succeeding article.

Basso-Rilievo, in *Sculpture;* that kind of sculpture in which the figures do not stand out from the ground in their full proportion: low or flat sculpture. All works in sculpture are classed as bassi-rilievi when the subjects represented are not isolated, but are adherent to the ground, whether they are of a similar or different material, and applied or fixed thereto; or form a part of the material in which they are wrought. This branch of the art is divided into three classes, called, alto-rilievo, mezzo-rilievo, and basso-rilievo.

Alto-rilievo is that relief in which the figures are entire, or nearly so, being attached only in a few places, and are relieved from the ground like the metopes of the Parthenon; mezzo-rilievo is that in which half the figure stands clear from the ground, and the other appears buried therein; and basso-rilievo, properly so called, is that in which the figures lose their projection, and are represented as nearly flat, like the Panathenæic procession of the same temple. Custom, however, has nearly abolished two of these terms; and basso-rilievo is often applied to each sort, be the projections what they may. The word anaglyphum, in the ancient writers, indicates a particular manner of this sort of sculpture, and is equivalent to the modern chasing or embossing; to which, when executed in metal, according to Cicero, was given the name of toreuma.

The true basso-rilievo, which has but small projection, requires more skill in the sculptor than that in which the projection is more considerable; because it is extremely difficult to give a natural effect to a figure which is of its proper height and size, but falls short of its real thickness. What is more difficult even than this, in the style of sculpture now under consideration, is picturesque composition in grouping the figures; because the artist cannot, as in painting, employ different back grounds remote from each other: and as the shadows in sculpture are real and not imitative, he must calculate his composition, and arrange its form for the light in which it is to be placed. The ancients used bassi-rilievi in decorating architectural designs, and in ornamenting their domestic furniture. All nations, however, in the history of the arts have used them, and they resemble in style that of their other works. The Egyptians ornamented their temples with an innumerable quantity of figures and hieroglyphics, of which the greater part have the outlines only sunk, and the area thus formed only painted; but many of them are of the class of bassi-rilievi. Their manner of executing these sculptures was singular: they first channelled an outline in the stone, and sunk it round the figure, so that it did not project beyond the original face; being, in fact, more a species of engraving than sculpture. The cabinet of the Royal Library at Paris possesses a very curious Egyptian sculpture thus wrought; and many of the same description are found in Egypt, principally on the frontispieces of the temples where the Scarabeus extends his reign.

The study of the ancient bassi-rilievi is of great service in the history of the arts; as from them may be collected many important facts of the mythology, customs, costume, &c. of the ancients. The finest collections of antique bassi-rilievi now existing, are those forming the Townly Collection, and now in the British Museum, ; the Elgin Marbles in the same place; the collections of Mr. Thomas Hope, Mr. Soane, the professor of architecture in the Royal Academy of London; and several fine casts in the Royal Academy. In Paris they had some fine antique bassi-rilievi in the Royal Museum; the Museum of the Augustins; and many private collections. The application of bassi-rilievi among the moderns is the same as among the ancients; being used in the decoration of public buildings, palaces, churches, triumphal arches, theatres, concert-

rooms, and private houses; furniture, tombs, and other subjects of ornamental architecture. The most celebrated specimens of basso-relievo (properly so called), of modern art in England, are those of the tympanum of the pediment of the East India House, by Bacon; the monument of Captain Miller, in a panel of St. Paul's Cathedral, by Flaxman: several others on the public monuments, erected in that cathedral and in Westminster Abbey, by Bacon, Banks, Bacon, jun., Rossi, Chantrey, Kendrick, Hopper, and Westmacott; and on the Continent, those of Baudurli, Ghiberti, and Lucca della Robbia, at Florence. Some of the finest bas-reliefs existing, are by Canova and Thorwaldsen. The bas-reliefs found by von Bröndstedt, Cockerell, &c., in the temple of Apollo at Phigalia, and sold to the British Museum for 15,000*l.* sterling, are celebrated, as are those on the column of Trajan.

Basset; the name of a game at cards, formerly much played, especially in France. It is very similar to the modern *faro*. Severe edicts were issued against it by Louis XIV., and it was afterwards played under the name of *pour et contre*. De Moivre, in his *Doctrine of Chances*, has calculated many problems connected with this game.

Basset-Horn, the richest of all wind instruments (called also *cornet*, by reason of its curvature), is believed to have been invented at Passau, in 1770. It was afterwards perfected by Theodore Lotz, in Presburg. It is, properly considered, an enlarged clarionet; and, notwithstanding the difference of its form, it resembles that, not only in its qualities and tone, but also as regards its intonation, the mode of holding it, and fingering; so that every clarionet-player can perform on it without practice. Besides the mouth-piece, by which the intonation is given, it is formed of five pieces—the head-piece (called the barrel), two middle pieces, the trunk and the bell, which is usually of brass. It has 15 ventages, of which four are provided with open, four with closed keys. Its compass is 3½ octaves, from lower F in the bass, to double C of the treble. It is seldom used in the orchestra; however, it is found in Mozart's Requiem and some other pieces. The basset-horn may also be used as a bass instrument.

Bassoon; an instrument which forms the natural bass to the hautboy. It is played, like that instrument, with a reed, and forms a continuation of its scale downwards. The reed is fixed to a crooked mouth-piece, issuing from the side of the bassoon. There, keys communicate to the ventages, which otherwise are too remote for fingering. It was formerly used as an accompaniment to the hautboy, from which it was termed *basson de hautbois*. But it is now so far improved with keys as to be susceptible of being played in solo. Its compass is three octaves, from double A in the bass to A in the second space of the treble; and its designation generally is the F or bass clef; yet, in the higher passages, for the more convenient arrangement of the notes, the alto, or tenor clef, is often used. It consists of four tubes, bound together like a faggot. Hence the Italians term it *fagotto*, and from them the Germans *fagott*. In music designed for wind instruments, it usually forms the bass. There is a modification of this instrument, much lower and stronger in its tones,—the bass-horn,—which, in field music, has of late been substituted for the serpent.

Bass-Viol; a stringed instrument, resembling, in form, the violin, but much larger. It has four strings and eight stops, which are subdivided into semi-stops, and is played with a bow.

Bastion (bulwark). In order to defend a place which is surrounded by a rampart and a ditch, it is necessary that every point at the foot of the rampart, in the ditch and before the citadel, should be, as much as possible, commanded by the cannon of the works. This is effected by breaking the line of fortification, so that a defence sideways may be attained. Before, and for some time after the invention of gunpowder, it was thought that towers, standing out from the wall, would answer this purpose; but these soon gave place to the spacious and projecting bastions or bulwarks, which consist of two flanks, that serve principally for the defence of the neighbouring bastions, and of two faces, which command the outworks and the ground before them. The wall between two bastions is called the curtain. These bastions are built in very different ways. Some are entirely filled with earth; some have a void space inside; some are straight, some curved, some double, some have even three or four flanks, one over the other; some have, and some have not, *fausse-brays* (see Fortification); sometimes they have casemates, destined for the retreat of the garrison, or for batteries; sometimes cavaliers, or orillons, &c. In modern times, among the fortifications built according to the system of bastions, those on the plan of Cormontaigne and the modern French works, are considered best adapted for defence. They are spacious; the flank of the side bulwark, which is perpendicular to the prolongation of the face of the principal bulwark, is not farther distant than a gunshot (300 paces) from its point; it is also straight, and orillons and other artificial contrivances are banished.

Bath. Bathing undoubtedly took place first in rivers and in the sea, but men soon learned to enjoy this pleasure in their own houses. Even Homer mentions the use of the bath as an old custom. When Ulysses enters the palace of Circe, a bath is prepared for him, after which he is anointed with costly perfumes, and dressed in rich garments. The bath, at this period, was the first refreshment offered to the guest. In later times, rooms, both public and private, were built expressly for the purpose of bathing. The public baths of the Greeks were mostly connected with the gymnasia, because they were taken immediately after the athletic exercises. The Romans, in the period of their luxury, imitated the Greeks in this point, and built magnificent baths. The following description applies both to the Greek and Roman baths:—The building which contained them was oblong, and had two divisions, the one for males, the other for females. In both, warm or cold baths could be taken. The warm baths, in both divisions, were adjacent to each other, for the sake of being easily heated. In the midst of the building, on the ground-floor, was the heating-room, by which not only the water for bathing, but sometimes also the floors of the adjacent rooms, were warmed. Above the heating-room was an apartment in which three copper kettles were walled in, one above another, so that the lowest was immediately over the fire, the second over the first, and the third over the second. In this way, either boiling, lukewarm, or cold water could be obtained. The water was carried, by separate pipes, provided with cocks, from these

kettles into the bathing-rooms, and a fresh supply was immediately poured into the kettles from a reservoir. Close to the heating-room were three separate rooms on each side, for the hot, the lukewarm, and the cold bath. The bathing-rooms had, in the floor, a bason of mason-work, in which there were seats, and round it a gallery, where the bathers remained before they descended into the bath, and where, also, the attendants were. There was also a sweating-room, which was heated by means of flues, and was called *laconicum*. This room had an opening in the ceiling, through which the light fell, and from which was suspended a brazen plate, that could be raised and let down at pleasure, to increase or lessen the heat. For undressing, for receiving the garments, and for anointing after bathing, there were different rooms; and connected with the bath were walks, covered race-grounds, tennis-courts, and gardens. These buildings, together with a number of bathing-rooms, were necessary for a public bath, which was adorned with splendid furniture, and all the requisites for recreation, and resembled, in its exterior appearance, an extensive palace. Roman luxury, always in search of means for rendering sensual enjoyments more exquisite, in later times, built particular conduits for conducting sea-water to the baths, used mountain snow, and enlarged these establishments in such a way that even their ruins excite admiration. (See Wichelhausen, *On the Baths of the Ancients*, Mannheim, 1807.) Among the Europeans, the Russians have peculiar establishments for bathing, which are visited by all classes of the people during the whole year. The Russian bath consists of a single hall, built of wood. In the midst of it is a powerful metal oven, covered with heated stones. Round about there are broad benches. In entering this hall, you encounter such a heat, that one who is not accustomed to it can bear it but a few moments. Those, however, who can endure it for some time, undress and stretch themselves on a mattress upon one of the benches. Cold water is then poured on the heated stones; a thick, hot steam rises, which envelopes the bather, and heats him to such a degree, that the perspiration issues from his whole body. The thermometer, in this steam, usually rises to 40° or 50° Réaumur (122° to 142° Fah.). After the Russian has enjoyed his bath in this way, he is gently whipped with wet birch rods, rubbed with soap, in order to lessen the perspiration, and, afterwards, washed with lukewarm and cold water; of the latter some pailsfull are poured over his head; or else he leaps, immediately after this sweating-bath, into a river or pond, or rolls in the snow. The Russian of higher rank takes, after his bath, a draught of English ale, white wine, toasted bread, sugar and citrons, and rests upon a bed. The common Russian, after having cooled himself in the snow, drinks some brandy, and goes again to his work. The people regard these baths as a necessary of life, and they are to be found in every village. They are also met with in Finland.—Among the Asiatics, baths are in general use. The Turks, by their religion, are obliged to make repeated ablutions daily: besides these, men and women must bathe in particular circumstances and at certain times. For this purpose, there is, in every city, a public bath connected with a mosque; and rich private persons possess private bath-houses, adorned with all the objects of Asiatic luxury. Besides these baths, the Turks have also the dry-bath of the ancients. The buildings which they use for this purpose, are built of stone, and usually contain several rooms, the floors of which are of marble. These rooms are heated by means of pipes, which pass through the walls, and conduct the heated air to every part in the most perfect manner. After undressing, they wrap themselves up in a cotton coverlet, put on wooden slippers, in order to defend the feet against the heat of the floor, and then enter the bath-room. The hot air soon produces a profuse perspiration; upon which they are washed, wiped dry, combed, and rubbed with a woollen cloth. At last, the whole body is covered with soap, or some other application, which improves the skin. After this bath, they rest upon a bed, and drink coffee, sherbet, or lemonade. The Turkish ladies daily bathe in this manner; the men not so frequently. A peculiar kind of baths is used in the East Indies, of which Anquetil gives the following account:—An attendant stretches the bather upon a table, pours over him warm water, and begins, afterwards, with admirable skill, to press and to bend his whole body. All the limbs are extended, and the joints made to crack. After he has done with one side, he goes on with the other; now kneels upon the bather; now takes hold of his shoulders; now causes his spine to crack, by moving the vertebræ; now applies gentle blows to the fleshy and muscular parts. After this, he takes a cloth of hair, and rubs the whole body, removes the hard skin from the feet with pumice-stone, anoints the bather with soap and perfumes, and finishes by shaving and cutting his hair. This treatment lasts about three-quarters of an hour, and produces the greatest refreshment. An agreeable feeling pervades the whole body, and ends with a sweet slumber of several hours. Public baths are common in Europe, and there are at present few cities without them. Medicine has been employed to increase the wholesome effects of baths by various compositions and methods of application. Baths are distinguished by the nature of the fluid, by the degree of heat, and by their influence upon the body. They are prepared with water, milk, wine, &c.; are of different temperatures; and herbs, iron, soap, and other substances are mixed with them, as the purpose requires. There are, also, baths of earth, sand, air, vapour, and electric baths. They are applied either to the whole body, or only to a single part. The shower-bath affords an agreeable and healthful mode of bathing, and much use is made of it in medicine. Mineral baths are those, the water of which naturally contains mineral ingredients.

Bath, *Knights of the*; a military order of England, concerning the origin of which antiquaries differ. It is certain that Henry IV., on the day of his coronation, conferred the degree upon 46 knights. From that time, the kings of England have bestowed this dignity previous to coronations, after births and marriages of the royal issue, &c. Charles II created several knights of the Bath, but after his time, the order fell into neglect, till 1725, when George I. revived it. By the book of statutes then prepared, the number of knights was fixed at 38, viz. the sovereign, and 37 knights-companions. The king allowed the chapel of King Henry VII., in Westminster Abbey, to be the chapel of the order. The Dean of Westminster is dean of the order. An esquire of the order is allowed to hunt and fish in the king's roy-

alty, and is exempted from serving in the office of high sheriff, and every parochial office. *K. B.* is the abbreviation for *Knight of the Bath*.

BATISTE; cambric; a very fine, thick, white, linen cloth. It is made of the best white flax, called *ramé*, which is cultivated in a district of France. In the 13th century, this manufacture is said to have been brought into vogue by Baptista Chambrai, in Flanders, and the linen afterwards received from him the name of *batiste*, or cambric (*toile de Chambrai*.) Others think that the first appellation is derived from the fine linen which we receive from India, where it is called *bastas*. Different kinds of batiste are called *linons*, *claires*, *cambrics*, &c., and manufactured not only in France and the Netherlands, but also in Switzerland, in Bohemia, and Silesia. The best come from India. (See CAMBRIC.)

BATTERING-RAM, see ARIES.

BATTERY, in the *military art*; 1. any raised place in which cannon are planted; 2. all the lines of a fortress, behind the parapets of which are cannon. They are erected in the open field, in citadels, on a lake or the sea, before a place which is to be besieged, &c. With regard to the kind of artillery, they are distinguished into cannon, howitzer, mortar, &c. With regard to their object, they are divided into breach batteries, used to attack the faces or salient angles of the bastion or ravelin, in order to make an accessible breach; batteries *en echarpe*, or oblique batteries, which are erected beside the breach batteries, under an angle of 20 to 30 degrees, in order to batter a breach obliquely; *ricochet* batteries, which command the enemy's lines, so that the balls roll along the whole length of the rampart, and render it insecure, &c. Their position is perpendicular to the line which is to be enfiladed. Mortar batteries have the parapets inwards, and no embrasures. In respect to their position, they are divided into horizontal, raised, and sunk batteries. The disposition of floating batteries may be various. Such a battery commonly consists of a raft, in the middle line of which cannon are placed, having before them breastworks made of bags of wool. The raft is fastened by a strong cable, to a beam or anchor, round which it is to be moved, and brought, by the aid of oars or rudders, to the proper place. In experimental physics, *battery* is a combination of several jars or metallic plates, to increase the effect of electricity and galvanism. (See ELECTRICITY.)

BATTLE. The object of a war may be obtained in two different ways: either one party forces the enemy, by skilful manœuvres, marches, demonstrations, the occupation of advantageous positions, &c., to quit the field (which belongs to the province of *strategy*); or the hostile masses approach each other (by design or by chance), so that a battle becomes necessary to determine which shall keep the field. The rules for insuring a successful issue, whether they respect the preparations for the conflict, or the direction of the forces when actually engaged, belong to *tactics*, in the narrower sense of the word. *Strategy* also shows the causes which bring armies together, and produce battles without any agreement between the parties. It belongs not to this article to explain this point. It may be sufficient to say, in general, that armies in their marches (and consequently in their meeting), are chiefly determined by the course of the mountains and rivers of a country. In ancient times and the middle ages, the battle-ground was often chosen by agreement, and then the battle was a mere trial of strength, a duel *en gros*; but, in our time, such trifling is done away.

War is now carried on for the real or pretended interest of a nation, or a ruler who thinks or pretends that his interest is that of the nation. Wars are not undertaken for the purpose of fighting, and battles are merely the consequence of pursuing the purpose of the war. They arise from one party's striving to prevent the other from gaining his object. Every means, therefore, of winning the battle is resorted to, and an agreement can hardly be thought of. In this respect, a land battle is entirely different from a naval battle. The former is intended merely to remove an obstacle in the way of gaining the object of the war; the destruction of the enemy, therefore, is not the first thing sought for. The views of one party can often be carried into effect with very little effusion of blood; and if a general can obtain the same end by manœuvring as by a battle, he certainly prefers the former. But the object of a naval engagement is, almost always the destruction of the enemy; those cases only excepted, in which a fleet intends to bring supplies or reinforcements to a blockaded port, and is obliged to fight to accomplish its purpose.—As the armies of the ancients were not so well organized as those of the moderns, and the combatants fought very little at a distance, after the battle had begun, manœuvres were much more difficult, and troops when actually engaged, were almost entirely beyond the control of the general. With them therefore, the battle depended almost wholly upon the previous arrangements, and the valour of the troops. Not so in modern times. The finest combinations, the most ingenious manœuvres, are rendered possible by the better organization of the armies, which thus, generally at least, remain under the control of the general. The battle of the ancients was the rude beginning of an art now much developed. It is the skill of the general, rather than the courage of the soldier, that now determines the event of a battle. There is, probably, no situation which requires the simultaneous exertion of all the powers of the mind more than that of a general at the decisive moment of a battle. While the soldier can yield himself entirely to the impulse of his courage, the general must coolly calculate the most varied combinations; while the soldier retreats, the general must endeavour to turn the tide of battle by his ardour or his genius. Daring courage, undaunted firmness, the most active and ingenious inventon, cool calculation and thorough self-possession, amid scenes of tremendous agitation, and under the consciousness that the fate of a whole nation may depend on him alone in the trying moment,—these are the qualities which a good general cannot dispense with for a moment. If it is the character of genius to conceive great ideas instantaneously, military genius is, in this respect, the greatest. Great generals have therefore been, in all ages, the objects of admiration; and as a great artist may be no example in a moral point of view, although we admire the genius displayed in his productions, so we cannot but bestow the same kind of admiration on the high intellectual gifts of a great general. Few situations, therefore, enable a man to acquire higher glory, than that of a great commander in a good cause.—If troops meet accidentally, and are thus obliged to fight, it is called a *rencontre*. Further, battles are distinguished into *offensive* and *defensive*.

Of course, a battle which is offensive for one side, is defensive for the other. Tacticians divide a battle into three periods—that of the disposition, that of the combat, and the decisive moment. The general examines the strength, reconnoitres the position, and endeavours to learn the intention of the enemy. If the enemy conceals his plan and position, skirmishes and partial assaults are often advisable, in order to disturb him, to obtain a view of his movements, to induce him to advance, or with the view of making prisoners, who may be questioned, &c. Since the general cannot direct all these operations in person, officers of the staff and aids assist him ; single scouts or small bodies are sent out, and spies are employed. Any person or thing (ministers, peasants, shepherds, maps, &c.), which can afford information of the enemy, or the ground on which the battle is likely to take place, is made use of for obtaining intelligence, by force or otherwise.

According to the knowledge thus acquired, and the state of the troops, the plan of the battle, or the disposition, is made; and here military genius has an opportunity to display itself. There is an immense difference between the quick, clear, and ingenious disposition of a great general, which shows the leading features of the plan to every commander under him, and provides for all cases, favourable or unfavourable, with a few distinct touches, without depriving the different commanders of freedom of action, and the slow, indistinct, minute, and after all, inaccurate dispositions of a feeble commander. Napoleon's dispositions are real masterpieces. Like a great artist, he delineates, with a few strokes, the whole character of the battle; and as the disciples of Raphael assisted in the painting of his pictures, but necessarily worked in the great style of their master, which his first lines gave to the picture, so all the skilful generals under Napoleon laboured for the accomplishment of one great end, sometimes disclosed to them, sometimes concealed in the breast of the commander. To the disposition also belongs the detaching of large bodies which are to co-operate in the battle, but not under the immediate command of the chief. The plan of the battle itself, the position of the troops, &c., is called the *order of battle* (*ordre de bataille*). This is either the parallel, or the enclosing (if the enemy cannot develope his forces, or you are strong enough to outflank him), or the oblique. When each division of troops has taken its position, and received its orders, and the weaker points have been fortified (if time allows it), the artillery placed on the most favourable points, all chasms connected by bridges; villages, woods, &c., taken possession of, and all impediments removed as far as possible (which very often cannot be done, except by fighting), then comes the second period—that of the engagement. The combat begins, either on several points at a given signal, as is the case when the armies are very large, and a general attack is intended; as, for instance, at Leipsic, where three fire-balls gave the signal for battle on the side of the allies; or by skirmishes of the light troops, which is the most common case. The artillery endeavours to dismount the batteries of the enemy, to destroy his columns, and, in general, to break a passage, if possible, for the other troops. The forces, at the present day, are brought into action mostly in columns, and not as formerly, in long, but weak lines. Here the skill of the commanders of battalions is exerted. Upon them rests the principal execution of the actual combat. The plans and order of a general reach only to a certain point; the chiefs of battalions must do the great work of the battle. Before the battle, the general places himself upon a point, from which he can see the conflict, and where he can easily receive reports—upon a hill, in a windmill, &c. Sometimes, if there is no such favourable point, a staging is erected. Napoleon stood upon such a one in the battle of Waterloo. A few men are near him, as his body-guard; others take charge of the plans and maps; telescopes are indispensable. He often sends one of his aids to take instant command of the nearest body of cavalry, in order to execute an order which must be carried into effect quickly. He receives the reports of the generals under him, and gives new orders; disposes of the troops not yet in action ; strengthens weak points; throws his force upon the enemy, where he sees them waver ; or changes if necessary, with a bold and ingenious thought, the whole order of battle. The general now uses every means to bring on the third period of the battle—the decisive moment. This cannot always be the result of combinations. It often takes place much sooner than was expected; it is often protracted by accidents, want of energy on the part of the commanders, &c.—Sometimes all the operations are drawing to the end which the general has been aiming to attain, when an unforeseen accident suddenly gives a new impulse to the enemy. Victory or defeat depend now upon one moment, one happy idea. Perhaps it is all important to break, at once, the enemy's centre; perhaps to concentrate the destructive power of the artillery, and, sweeping away some obstacle, to send, as Napoleon often did, a torrent of cavalry upon a certain point. Any thing which can carry disorder into the ranks of the enemy is of great use. If he begins to waver, or to retreat in order, or fly in disorder, it is always necessary to follow up the victory with all possible vigour and celerity. This is as important as victory itself. Napoleon was, till the last war in Germany, a master in this particular. There are three maxims as important for the general as they are simple:—1. Know your enemy, his strength and intentions: 2. make all the operations and manœuvres of the parts coincide, as much as possible, with the great plan of the battle; 3. pursue victory to the utmost. It is also a maxim, in regard to battles, as well as to the conduct of war generally, to make the enemy conform to your plans, and to avoid the necessity of accommodating yourself to his. (See the second division of this work, in which examples will be given illustrative of the most celebrated engagements in ancient and modern times.)

BATTLE AXE; a weapon much used in the early part of the middle ages, particularly by the people who fought on foot. It was not uncommon, however, among the knights, who used also the mace, a species of iron club or hammer. Both are to be seen in the different collections of old arms in Europe. Both these weapons, and another kind, called in German *Morgenstein* (morning star), consisting of a staff, having an iron ball at the end, with cross iron spikes, served to give stunning blows, whose force was felt through the iron armour of the knights. Knights used chiefly the *Morgenstein* and the mace. The Greeks and Romans did not employ the battle-

axe, though it was found among contemporary nations. In fact, the axe is one of the earliest weapons, its use, as an instrument of domestic industry, naturally suggesting its application for purposes of offence; but, at the same time, it will always be abandoned as soon as the art of fencing, attacking, and guarding is the least cultivated; because the heavier the blow given with this instrument, the more will it expose the fighter. It is a weapon which affords hardly any guard, and it never would have remained so long in use in the middle ages, had it not been for the iron armour, which protected the body from every thing but heavy blows. In England, Ireland, and Scotland, the battle-axe was much employed. At the battle of Bannockburn, king Robert Bruce clove an English champion down to the chine with one blow of his axe. A blow of equal force was given by a Suabian knight, in the Levant, in presence of the German emperor. The Lochaber axe remained a formidable implement of destruction in the hands of the Highlanders nearly to the present period, and is still used by the city guard of Edinburgh in quelling riots, &c.

Battle-Piece; a painting which represents a battle, exhibiting large masses of men in action. The armour of the ancients, and the whole array and action of their battles, afford subjects much more favourable to the artist than the straight lines, or condensed columns, and the fire-arms of the moderns. A painter of battle-pieces ought to have an accurate knowledge of the appearance of horses and men, and, if possible, to have seen a battle, as few persons are able to form from hearsay an accurate idea of such a scene. Some of the greatest pieces of this kind are, the battle of Constantine, of which the cartoons were drawn by Raphael, and which was executed by Giulio Romano; Lebrun's battles of Alexander, and the battles of the Amazons, by Rubens. From these may be distinguished the skirmishes, surprises, &c., which are represented with so much skill by Antonio Tempesta, John Snellink, Jos. van der Velde, John Asselyn, Peter Sneyers, Robert van Hoek, Fulcone, called *oracolo delle battaglie*, James Courtois, Francis van der Meulen, Philip Wouvermann, Charles Breydel, Henry Verschuuring and, George Philip Rugendas.

Bayonet. This is the name of the iron blade, formed like a dagger, and placed upon the muzzle of the musket, which is thus transformed into a thrusting weapon. It was probably invented, about 1640, in Bayonne, and was used in the Netherlands, in 1647, but was not universally introduced until after the pike was wholly laid aside, in the beginning of the 18th century. Since the general war in Europe, some officers have adopted the idea of former military writers (for instance, Guibert), of increasing the efficiency of the bayonet by a more regular exercise of the infantry in its use. A Saxon captain, von Selmitz, has the merit of having first developed this idea in a systematic treatise. As cavalry are often counted by horses, infantry are sometimes counted by bayonets.

Beam, in *Architecture;* a long and large piece of timber, into which the feet of the principal rafters, king posts, &c., are framed; intended also to tie the walls of the building together; contradistinguished from those used in the floors, which are called girders, and those which are used to support the fronts of houses, which are called brestsomers.

Bear, in *Astronomy;* a name given to two constellations called the greater and the lesser bear, or ursa major and minor.

The polar star is said to be in the tail of the lesser bear; this star is never above two degrees distant from the north pole of the world. (See Ursa.)

Beer; a fermented liquor, made from any farinaceous grain; but generally from malted barley. This is effected by extraction with water and fermentation. With this view, a quantity of malt freed from its germs, and sufficient for one brewing, is coarsely bruised by grinding, and being placed in the mash-tub, after being well mixed with tepid water, its temperature is considerably raised. When the whole mass has been well stirred, and then allowed to subside, the extract (mash), or sweet-wort, is brought into the boiler; and the malt remaining in the tub, is once more extracted by infusion with hot water. This second extract, treated in like manner, is added to the first, and both are boiled together. This clear infusion is now drawn off, and called boiled wort. To render the beer fitter for digestion, as well as to fit it for the market, hops are added. After which it ought to be quickly cooled, to prevent its transition to the acetous fermentation, which would ensue, if it were kept too long at a high temperature. On this account, the wort is transferred into the cooler; where it is exposed with a large surface to cold air, and from this to the fermenting-tub, that by the addition of a sufficient portion of recent yeast it may begin to ferment. When this fermentation has proceeded to a due degree, and the yeast ceases to rise, the beer is conveyed into casks, placed in cool cellars, and the fermentation completed. It now becomes what is called "barrelled beer," with the precaution of occasionally filling up the vacancy caused in the vessel by evaporation. Or, the beer is bottled before it has done fermenting; and the bottles are stopped a little before the fermentation is completely over. By so doing, the bottled beer is rendered sparkling. In this state it frequently bursts the bottles, by the disengagement of the carbonic acid gas which it contains; and it effervesces like champaign, when brought into contact with air, on being poured into another vessel.

Beer, well prepared, should be limpid and clear, possess a due quantity of spirit, excite no disagreeable sweet taste, and contain no disengaged acid. By these properties it is a species of vinous beverage, and is distinguished from wine, in the strict sense, and other liquors of that kind, by the much greater quantity of mucilaginous matter which it has received by extraction. "Brown beer" derives its colour from malt highly dried in the kiln, and its bitterish taste from the hops. "Pale beer" is brewed from malt still lower dried.

In the above notice we have confined ourselves to the simplest process for the brewing beer. *Porter* fitted for the London market is a very different compound, and will be described under that head.

Bell, a vibrating instrument, ranked by musicians among the number of musical instruments of percussion. The parts of a bell are the body or barrel, the clapper within side, and the suspending links. It is usually formed of a compound, called bell-metal. The thickness of its edges is usually 1-15th of its diameter, and its height twelve times its thickness. The bell-founders have a diapason, or bell-scale, with which they measure the size, thickness, weight, and tone of their bells.

The sound of a bell arises from a vibratory motion of the parts thereof, much like that of a musical chord. The stroke of the clapper, it is obvious, must change the figure of the bell, and from a round make it oval; but the metal having a great degree of elasticity, that part which the stroke drove farthest from the centre will fly back again, and this even somewhat nearer the centre than before; so that the two points, which before were the extremes of the longer diameter, now become those of the shorter. Thus, the circumference of the bell undergoes alternate changes of figure, and gives that tremulous motion to the air, in which sound consists.

M. Penault maintains, that the sound of the same bell or chord, is a compound of the sound of the several parts thereof; so that where the parts are homogeneous, and the dimensions of the figure uniform, there is such a perfect mixture of all these sounds, as constitutes one uniform, smooth, even sound; and the contrary circumstances produces harshness. This he proves from the bell's differing in time according to the part you strike; and yet strike it any where, there is a motion of all the parts. He therefore considers bells as composed of an infinite number of rings; which, according to their different dimensions, have different tones, as chords of different lengths have; and when struck, the vibrations of the parts immediately struck determine the tone being supported by a sufficient number of consonant tones in the other parts. Mr. Hawksbee, and others, have found, by experiment, that the sound of a bell struck under water, is a fourth deeper than in the air; though Mersennus says, it is of the same pitch in both elements. This writer has treated largely of the different metals of which bells are formed, of their figure, crassitude, and degrees of ponderosity, as they respect each other in a given series.

Bells are observed to be heard farther, placed on plains, than on hills; and still farther in valleys, than on plains: the reason of which it will not be difficult to assign, if it be considered that the higher the sonorous body is, the rarer is its medium; consequently the less impulse it receives, and the less proper vehicle it has to convey it to a distance. There is a curious observation in a paper of M. Reaumur's, in the *Memoirs of the Paris Academy*, relating to the shape most proper for bells, to give them the loudest and clearest sound. He observes, that as pots, and other vessels more immediately necessary for the service of life, were doubtless made before bells, it probably happened, that the observing these vessels to have a sound when struck, gave occasion to making bells, intended only for sound, in that form: but that it does not appear that this is the most eligible figure; for lead, or metal, which is, in its common state, not at all sonorous, yet becomes greatly so on being cast into a particular form, and that very different from the common shape of bells.

In melting lead for the common occasions of casting in small quantities, it is usually effected in an iron ladle; and as the whole is seldom poured out, the remainder, which falls to the bottom of the ladle, cools into a mass of the shape of that bottom. This is, consequently, a segment of a sphere, thickest in the middle, and thinner towards the edges: nor is the ladle any necessary part of the operation, since, if a mass of lead be cast in that form in a mould of earth or sand, in any of these cases it is found to be very sonorous. Now, if this shape alone can give sound to a metal, which in other forms is perfectly mute, how much more must it necessarily give it to other metals naturally sonorous in whatever form. It should seem that bells would much better perform their office in this than any other form, and that it must particularly be a thing of great advantage to small bells of common house-clocks, which are required to have a shrill note, and yet are not allowed any great size. M. Reaumur very judiciously observes, that if our forefathers had opportunities of being acquainted with the sound of metals in this shape, we should probably have had all our bells at present of this form.

With regard to the origin of bells, those of a small size are very ancient; but those of a large bulk, hung in towers and hung by ropes, were introduced at a much later period. Among the Jews, it was ordained by Moses, that the lower part of the blue robe which was worn by the high-priest in religious ceremonies, should be adorned with pomegranates and gold bells intermixed at equal distances.

The kings of Persia are said to have had the hem of their robes adorned, like that of the Jewish high-priests, with pomegranates and gold bells. The Arabian princesses wear on their legs large hollow gold rings, filled with small fruits, which sound like bells, when they walk; and these, with similar appurtenances, give notice that the mistress of the house is passing, so that the servants of the family may behave with respect, and strangers may retire to avoid seeing the person who advances. Calmet supposes, that it was with some such design of giving notice that the high-priest was passing, that he wore little bells at the hem of his robe; and it was also a kind of public notice that he was about to enter into the sanctuary.

In the court of the king of Persia, no one entered the apartments without some warning; and thus the high-priest, when he entered the sanctuary, desired permission to enter by the sound of his bells, and in so doing, he escaped the punishment of death annexed to an indecent intrusion. The prophet Zacharias speaks of bells of the horses, which were probably hung to the bridles or foreheads of war-horses, that they might thus be accustomed to noise. Among Christians, they were first employed to call together religious congregations, for which purpose runners had been employed before. Afterwards the people were assembled by the sound of little pieces of board struck together; hence called *sacred boards.* To the present day, the Catholics use such boards in Passion-week and Lent, because the noise of bells seems to them unsuited to the solemnity of the season. On the first day of Easter the bells ring again, and the return of the accustomed sound produces a very cheerful effect. Paulinus, bishop of Nola in Campania, is said to have first introduced church bells, in the fourth century, and thence the Latin names of the bell, *campana* and *nola,* are said to have originated. In the sixth century bells were used in the convents; they were suspended on the roof of the church in a frame. Towards the end of this century bells were placed on some churches at the expense of certain cities. About 550 they were introduced into France. Pope Sebastian, who died in 605, first ordered that the hours of the day should be announced by striking the bell, that people might better attend to the *horæ canonicæ*, that is, to the hours for

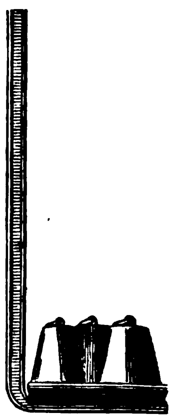
singing and praying. In 610, Clothaire besieged Sens, when Lupus, bishop of Orleans, ordered the bells of St. Stephen to be rung. The sound so frightened Clothaire, that he gave up the siege. In the eighth century, the custom of baptizing and naming bells began. Church bells were probably introduced into England soon after their invention. They are first mentioned by Bede, about the close of the seventh century. In the East they came into use in the ninth century; in Switzerland, in 1020; at what period they were brought into Germany is uncertain. In the 11th century the cathedral at Augsburg had two bells. The same spirit which induced people to build immense minsters, and to apply their wealth n ornamenting the places of worship, made them vie with each other in the size of their bells. The great bell of Moscow, cast in 1653, in the reign of the empress Anne, is said by Mr. Clarke, to be computed to weigh 443,772 lbs. A bell in the church of St. Ivan, in the same city, weighs 127,836 lbs.; another, 356 cwt.; and the one cast in 1819 weighs 1600 cwt., the clapper alone weighing 18 cwt. On the cathedral of Paris a bell was placed in 1680, which weighed 340 cwt., and measured 25 feet in circumference. In Vienna a bell was cast, in 1711, of 354 cwt. In Olmütz is one of 358 cwt. The famous bell at Erfurt, in Germany, which is considered to be of the finest bell-metal, having the largest proportion of silver in it, and is baptized *Susanne*, weighs 275 cwt., is more than 24 feet in circumference, and has a clapper of 4 feet, weighing 11 cwt. Great Tom, of Christ Church, Oxford, weighs 17,000 lbs.; of Lincoln, 9894 lbs.; the bell of St. Paul's, London, 8400 lbs.; a bell at Nankin, in China, is said to weigh 50,000 lbs.; and seven at Pekin, 120,000 lbs. each The inscriptions on old bells are curious, and in some cases, have even historical value; and, at this time, when curiosities of all kinds are eagerly sought for, a collection of these inscriptions would not be uninteresting. The different uses of bells have given rise to many poems, some of which are inscribed on the bells themselves. One of the most common is the following:

> Funera plango, fulgura frango, sabbata pango
> Excito lentos, dissipo ventos, paco cruentos.

Perhaps the finest poem which has ever been written on bells is Schiller's poem, *Die Glocke* (The Bell), in which he describes the casting of the bell, and all its uses, in a highly poetical manner. This has been translated into many languages, and lately into Greek and Latin, by a professor at Liege.

Bellows; a machine so formed as to exhale and inhale air by turns, by the enlargement and contraction of its capacity. As soon as men began to make use of fire, the importance of bellows was felt, since the natural bellows, if we may give this name to the lungs, could not be applied to any great extent. The invention of bellows is ascribed to Anacharsis, the Scythian. Probably, this invention, like so many others, took place in different countries, since the want which occasioned it is universal. The first deviation from the ancient, and still common form of the bellows, was made by the Germans about 100 years ago, and the forms at present are very various, as many attempts have been made for the improvement of this highly important machine, which becomes necessary wherever a powerful flame is required in the arts. As mining is carried on extensively in Germany, and great heat is required in smelting the ores, and working the metals, many new kinds of bellows have been invented in that country, of which we only mention that of Mr. Von Baader, in Munich. It consists of an empty box, which moves up and down in another, partially filled with water. Between the bottom of the empty box and surface of the water is a space filled with air, which is driven out by the descent of the enclosed box. Bellows of very great power are generally called *blowing-machines*. One of the largest is that recently erected in England, at the smithery in the king's dock-yard, at Woolwich. It is adequate to the supply of air for forty forge fires, amongst which are several for the forging of anchors, iron knees, and many other heavy pieces of smithery. The common Chinese bellows consist of a box of wood about two feet long, and one foot square, in which a thick, square piece of board, which exactly fits the internal cavity of the box, is pushed backwards and forwards. In the bottom of the box, at each end, there is a small conical or plug valve to admit the air, and valves above to discharge it.

Bellows, *Hydrostatic*, is a machine constructed expressly for the purpose of showing in the most striking manner that the pressure of fluids is as their perpendicular heights, and that a quantity, however small, may be made to support a weight, or another quantity, however large.



This machine is represented in the accompanying figure; it consists of two circular boards, about twenty inches in diameter; these boards are connected by means of strong leather, which entirely surrounds them, and permits them to open and close like a pair of common bellows, with this difference, that they open equally all round, and therefore the boards always remain parallel to one another. The leather, at its junctures, is well secured, and the whole machine is water-tight. In the under board is fixed a pipe communicating with the interior, and reaching to a considerable height above. Through this pipe let some water be poured into the bellows, and the upper board will be observed to rise a little; place a weight of 100 pounds upon it, pour in more water, and it will be found no obstruction to its rising further; increase the weight to 300 pounds, and the pressure of the water in the tube will overbalance the whole; add water, till the leathers are at their utmost extension; the water will then fill in the tube, and the upper board cannot be depressed, nor the water forced out of the small tube, until the pressure upon it is more than that of a column of water, whose diameter is equal to that of the interior of the bellows, and its height equal to that in the tube; by increasing therefore the length of the tube, a most enormous weight might be raised by the pressure of a few ounces of water.

The principle of the hydrostatic bellows has been applied in the invention of a very valuable machine called the *Hydrostatic Press*, which see.

Bend Dexter, in *Heraldry*; is one of the nine ordinaries, and occupies one-third of the escutcheon when charged, and one-fifth when plain; it consists

of two equal lines, drawn diagonally from the dexter chief to the sinister base of the shield. This ordinary has more subdivisions or diminutives than any of the others, viz. bendlet, gortier, and ribbon, none of which diminutives can properly be charged.

Benzoic Acid is obtained by the application of a moderate heat to the balsam of Peru: it rises in vapour, and condenses in slender prisms, which are white and brilliant. It has a peculiar aromatic odour. When heated on burning fuel, it inflames and burns with a clear yellow light. It unites with alkalies and earths, forming salts called *benzoates*, which are unimportant, except the benzoate of iron, which, from its insolubility, affords a convenient means of separating iron from its solutions, so as to ascertain its quantity, and also of obtaining it free from manganese, which forms with the acid a soluble salt.

Benzoin is a solid, fragile, vegetable substance, of a reddish-brown colour. In commerce, two varieties are distinguished, viz. the common and the amygdaloidal; the latter containing whitish tears, of an almond shape, diffused through its substance. It is imported from Sumatra, Siam, and Java, and is found also in South America. Benzoin is obtained from the tree called *styrax benzoin*, and perhaps from some others. On making incisions into the bark, it flows out in the form a balsamic juice, having a pungent taste, and an agreeable odour. The pure balsam consists of two principal substances, viz. a resin, and a peculiar acid termed *benzoic*, which is procured from the mass by sublimation. It is soluble in water. This acid is found, also, as a constituent principle in storax and the balsams of Tolu and Peru: it exists in the urine of cows, camels, and even of young children. It is sometimes found in a crystalline form on the pods of the vanilla. Benzoin is not soluble in water, but is readily dissolved in alcohol, by the aid of a gentle heat. The tincture thus made is used in pharmacy. A small quantity of this tincture, dropped into water, forms a white, milky fluid, which is used in France as a cosmetic, under the name of *lait virginal*. The gum is a principal ingredient of the common court plaster. The acid, as well as the gum, is employed in medicine: they are stimulating, and act more particularly upon the pulmonary system; whence they are used in asthma and chronic catarrh.

Bergamotte; a certain fragrant and cordial essence, extracted from a kind of lemon in Italy; the fruit of a lemon tree ingrafted on a Bergamot pear tree. The liquor is an ætherial oil, very subtile, and of an agreeable smell. Medicinally it operates on the heart, the stomach, and the head.

Berguet, in *Commerce;* a weight of 173 pounds, by which hemp and other goods are sold in Russia.

Beryl; a beautiful sea-green colour, for the use of artists, is prepared under this name. We referred to it under the name of Aqua Marina, from which it is erroneously supposed to be made. It is very costly, and rarely found of a durable quality.

Bessich; a tin coin at Orinus, in value much less than a farthing.

Bevel, or Bevil, in *Architecture;* any angle that is not a right angle or square, or is more or less than 90 degrees; but if it has an angle of 45 degrees, it is called a mitre. Also an instrument resembling a square and the mitre, but having its blade moveable for the proper adjusting of angles for the workmen. It differs from the square and the mitre, the blades of which are fixed at their relative degrees of aperture.

Bezant; round, flat pieces of pure gold, without any impression, supposed to have been the current coin of Byzantium. This coin was probably introduced into coat-armour by the Crusaders. Doctor Henry, in his *History of England*, estimates its value at 9*s*. 4½*d*. sterling. The gold offered by the king of England on the altar, at the feast of the Epiphany and the Purification, is called *bezant*.

Bezel, or Bezil, in *Architecture;* the upper part of the collet of a ring, which encompasses and fastens the stone in it.

Bezoar; a medicinal stone brought from the East and West Indies, which was formerly reckoned a sovereign antidote against poisons. It is found to be a morbid concretion in the stomachs of some animals, which consists partly of bile and partly of resin. The bezoars are distinguished into Oriental bezoar; found in the stomach of an animal of the goat kind in Persia, called pazan. Occidental bezoar, found in quadrupeds of the deer kind. Bezoar hystricus, found in the gall-bladder of the Indian porcupine. Monkey bezoar, found in certain monkeys of Brazil. German bezoar, found in the stomach of the chamois.

Bice, in *Painting;* a pale blue colour, which is prepared from the lapis armenius (smalt), and is inclined to be sandy. Bice requires good and careful grinding, and after ultramarine (which is too expensive for common use), it is one of the best of blues. A green colour formed by mixing the blue with orpiment, bears the same name; as do also certain compositions of indigo and verditer with chalk.

Biceps (bicapital, or double-headed); an epithet for several muscles having two heads, as, biceps cubiti, a muscle of the elbow, the outermost head of which rises from the acetabulum scapulæ. Biceps femoris, which rises from the protuberance of the ischium, on the back part. Its office is to bend the tibia. Biceps humeri, or biceps flexor, rising by one head from the glenoid cavity, by the other from the caracoid process. It acts both as a flexor and a rotator.

Bigot, in *Commerce;* a Venetian liquid measure, containing the fourth part of the amphora, or half the boot.

Bile; a yellowish-green liquid substance, of a bitter taste. Man and many animals have, on the inferior surface of the liver, a peculiar bladder, in which the bile, formed by the liver from the blood, is preserved. It consists of water and several other substances. The water constitutes the greatest part, and keeps the other parts in a state of solution. The remaining ingredients are a yellow, very bitter, fusible resin, which contributes most to the taste of the bile; a small portion of natron; some mineral alkaline salts; some oxide of iron; a small quantity of a yellowish substance, which is only partly dissolved in the natron; and a considerable portion of albumen. Thenard and Berzelius have done much to determine the ingredients of the bile. Its principal use seems to be, to separate the excrement from the chyle, after both have been formed, and to produce evacuations from the body. It is probable that these substances would remain mixed together, and they would, perhaps, even be partly absorbed together, were it not for the bile, which seems to combine with the excrement, and, by this combination, to facilitate its separation from the chyle, and thus to prevent its

absorption. Fourcroy supposes that the bile, as soon as it is mixed with the contents of the intestinal canal, suffers a decomposition; that its alkali and saline ingredients combine with the chyle, and render it more liquid, while its albumen and resin combine with the excrementitious matters, and gradually render them less fluid. From the late experiments of Berzelius, it cannot be doubted that the constituents of the bile are to be found in the excrementitious matter; so that the ingenious theory of Fourcroy is so far probable. The bile also stimulates the intestinal canal, and causes it to evacuate its contents sooner than it otherwise would do; for when there is a deficiency of bile, the body is constantly costive. Biliary calculi, or gall-stones, are sometimes found in the gall-bladders of men and animals. They are more rarely met with in the substance and body of the liver. Those that are found in the human subject consist, principally, of that peculiar substance, called, by Fourcroy, *adipocire*. They are of a white, grayish-brown, or black colour. The calculi found in the gall-bladders of quadrupeds have been thought to consist almost entirely of inspissated bile; but, though much less complicated than the corresponding concretions in the human subject, they must contain something more than the inspissated fluid, since they are insoluble, both in alcohol and water. (See JAUNDICE, and FEVER, BILIOUS.)

BILIARIS CALCULUS, in *Medicine*; the professional term for the gall-stone.

BILL, in *Agriculture*; an edged tool of the axe kind, with a hooked point, fitted to a handle, and used to lop boughs off trees, &c. When short, it is called a "hand-bill;" when long, a "hedge-bill."

BILLIARDS; a very interesting game, contributing also to health by affording the body moderate exercise. It was originally invented in France, whence it was introduced into the different nations of Europe. It is generally practised in almost all civilized countries, and affords a very agreeable recreation and amusement. The rules for the different games of billiards are too numerous to be given here. They are also generally found in billiard rooms. We therefore omit them, although we usually give the rules of games, in order to furnish a means of reference in doubtful cases. They may be found in *Hoyle's Games*.

BINNACLE, or BITTACLE; a case or box which contains the compass for steering a ship, and lights to show the compass at night. In ships steered by a wheel, it is common to have two binnacles, or a double binnacle, for the convenience of the steersman, on either side of the wheel; but, in this case, the compasses affect each other's direction, and thus render the ship's course uncertain.

BINOMIAL; an algebraic expression consisting of two terms; thus, $x+a$, $x-a$ are binomials.

BINOMIAL THEOREM, the general algebraical formula for the developement of any power of a binomial, or its expression, in a series consisting of single terms.

A *power* of a number is the phrase employed in mathematical language to denote the result of the multiplication of that number by itself as many times as are indicated by the degree of that power; the obvious mode, therefore, of *raising a number to any power*, is to multiply it successively by itself the requisite number of times. If we proceed in this manner, we may obtain the following powers of the binomial $x + a$.

$$(x+a)^2 = x^2+2ax=a^2,$$
$$(x+a)^3 = x^3+3ax^2+3a^2x+a^3,$$
$$(x+a)^4 = x^4+4xx^3+6a^2x^2+4a^3x+a^4,$$
$$(x+a)^5 = x^5+5ax^4+10a^2x^3+10a^3x^2+5a^4x+x^5.$$

This table might be continued to an indefinite extent; the examples we have given are, however, sufficient for our purpose. We see that the multiplication of $x+a$ by itself once, produces $x^2+2ax+x^2$; and as x and a represent no particular numbers, this product, which is the square of their sum, is a general expression for the square of the sum of any two numbers. For the same reason, the multiplication of this binomial by itself two, three, and four times respectively, or the performance of the operations indicated by $(x+a)^3$, $(x+a)^4$ and $(x+a)^5$, furnishes us with general expressions for the third, fourth, and fifth powers of the sum of any two numbers. But each of these expressions is, we perceive, different; the *law of composition*, as it is termed, of one power, is peculiar to that power, and applies to no other. The square of the sum of two numbers is not composed of *the cube of the first, plus three times the product of the second by the square of the first, plus three times the product of the first by the square of the second, plus the cube of the second;* nor is their cube made up of *the square of the first, plus twice the product of the first and second, plus the square of the second.* Unless, therefore, we can discover some general principle which regulates the formation of all powers of a binomial, we must necessarily have a separate expression for each power; and as the number of powers is of course indefinite, so must also be that of the expressions. A formula has, however, been invented, which is universally applicable to all powers of a binomial, and which embraces the law of composition of every one of them; this formula is termed the *Binomial Theorem*, and its demonstration is the subject of the present article.

It will, indeed, at once be seen that in each of the expressions which we have already obtained, the exponents of the letters of the different terms obey the same simple law; but it is not so easy to perceive that one common principle regulates their numerical coefficients. This was, however, ascertained by Newton, who discovered the existence of a certain relation between the coefficient of any term, and the coefficient and exponent of the one preceding, which enabled him at once to raise a binomial to a power of any given degree, without being compelled to ascend to it gradually through all the inferior degrees, or even to have recourse to the general formula. On the subject of the reasonings by which he was led to the discovery of this law, Newton has left us no information; he appears, indeed, from his own account,* to have sought it empirically, and to have formed it from an investigation of particular cases; but it has since been rigidly established, as a universal law, in a variety of ways. Of the different demonstrations which exist, the most elementary is that founded on the theory of combinations; therefore, in the following investigation, we necessarily presume the reader to be acquainted with that theory, for an explanation of which we refer to the article PERMUTATIONS and COMBINATIONS.

It may be advisable to recapitulate some of the results which are there obtained. The number of

* In a letter dated October 24, 1676, which he addressed to Oldenburg, one of the secretaries of the Royal Society, to be transmitted by him to Leibnitz. It is that numbered LV. in *Collin's Commercium Epistolicum.*

combinations of which m letters are susceptible, taken two at a time, is expressed by $\frac{m.(m-1)}{1.\ 2}$; taken three at a time, by $\frac{m.(m-1).\ (m-2)}{1.\ 2.\ 3.}$; four at a time, by $\frac{m.\ (m-1.\ (m-2).\ (m-3)}{1.\ 2.\ 3.\ 4}$, and generally, when taken n at a time, by

$$\frac{m.\ m-1.\ m-2\ \ldots\ldots\ldots\ m-n+1}{1.\ 2.\ 3.\ \ldots\ldots\ n}$$

Or, if $\frac{P}{Q}$ represent the number of combinations of m letters taken $n-1$ at a time.

$$\frac{P\ (m-n+1)}{Q\ n}$$

will express those of the same number of letters taken n at a time. These formulæ should be well understood and remembered, as they are of essential importance in the investigation to which we now proceed.

We remarked, that it was not easy to recognise any common principle which regulated the formation of the numerical coefficients of the terms of all the different powers of the binomial $x+a$. If we reflect for a moment on the nature of the process of multiplication, we shall perceive that these coefficients arise from the reduction that takes place between the like terms which must necessarily occur in a product resulting from the multiplication of factors which are all equal. This will at once be rendered apparent by performing, at full length, some one of the operations by which we have obtained those powers,—that of the square or second power, for instance:

$$\begin{array}{l} x+a \\ x+a \\ \hline x^2+ax+a^2 \\ \hline x^2+ax+ax+a^2=x^2+2\,ax+a^2. \end{array}$$

Here, in consequence of the similarity of the two factors $(x+a)$, $(x+a)$, the term ax occurs twice in their product, once as the result of the multiplication of a in the multiplicand by x in the multiplier, and again, as the result of multiplication of x in the multiplicand by a in the multiplier. The simplification of the product produces the numerical coefficient 2. But let us alter the second term of one of the factors, and for a substitute b; there will then be no two terms in both which are similar, therefore we shall have no like terms, and consequently no numerical coefficient in their product. We have

$$(x+a)\ (x+b)=x^2+ax+bx+ab,$$

or, collecting all the terms containing the same power of x into the same column, the product becomes,

$$\begin{array}{l|l} x^2+a & x+ab \\ \quad\ +b & \end{array}$$

This dissimilarity of the factors renders the law of composition of the product of two binomials more apparent than in the disguised form in which that product is obtained, when those factors are alike; hence, our investigation of this law will be greatly facilitated by observing its character when it occurs in that more undisguised state. To each of the binomial factors then, which we employ, let us give a different second term; that is to say, for $(x+a)$ $(x+a)$ or $(x+a)^2$, let us substitute $(x+a)\ (x+b)$; for $(x+a)^3$, $(x+a)\ (x+b)\ (x+c)$; for $(x+a)^4$, $(x+a)\ (x+b)\ (x+c)\ (x+d)$, and so on. We shall thus obtain the following results, according to the ordinary rules of algebraical multiplication:

$$\begin{array}{ll} & x+a \\ & x+b \\ \hline (1.)\ .. & \begin{array}{l|l} x^2+a & x+ab \\ \quad\ +b & \end{array} \\ & x+c \\ \hline (2.)\ .. & \begin{array}{l|l|l} x^3+a & x^2+ab & x+abc \\ \quad\ +b & \quad\ +ac & \\ \quad\ +c & \quad\ +bc & \end{array} \\ & x+d \\ \hline (3.)\ .. & \begin{array}{l|l|l|l} x^4+a & x^3+ab & x^2+abc & x+abcd \\ \quad\ +b & \quad\ +ac & \quad\ +abd & \\ \quad\ +c & \quad\ +ad & \quad\ +acd & \\ \quad\ +d & \quad\ +bc & \quad\ +bcd & \\ & \quad\ +bd & & \\ & \quad\ +cd & & \end{array} \end{array}$$

The expressions (1), (2), (3), are the products respectively of two, three, and four binomials; for convenience, we have arranged all the terms of each, which contain the same power of x in the same column, writing that power itself only once. This method is much more convenient than that of disposing those terms in the same horizontal line, for instance, than the arrangement of $abx+acx+bcx$, in the form of $(ab+ac+bc)\ x$. In either case, the expression is considered as a single term, in this particular example, made up of the factors $(ab+ac+bc)$ and x; and $ab+ac+bc$ is called the coefficient of x in that term. If we now examine these products, we shall observe the following law to regulate the formation of each:

1°. The exponent of x in the first term is equal to the number of binomials multiplied; in the second, it is one less than that number, and each succeeding term it decreases by unity, until in the last it becomes equal to zero. It follows from this observation, that the number of terms (in the extended sense of the word) in each product is greater by one than the number of binomials, whose multiplication gives that product.

2°. The coefficient of x in the first term, or that containing the highest power of that letter, is unity; in the second, whose exponent is one less than that of the first, it is equal to the sum of the second terms of all the binomial factors; in the third, whose exponent is two less than that of the first, to the sum of the different products obtained by the multiplication of every two of those second terms; in the fourth, whose exponent is three less than of the first, to the sum of all the products of every three of them, and so on.

3°. The last term is equal to the product of all the second terms of the binomials.

We have thus found a certain law to regulate the formation of the respective products of two, three, and four binomials. Were we to examine those resulting from the multiplication of five, six, seven, or eight, and the binomials, we should find them all to obey a law precisely similar. Hence, we might from analogy conclude, that the same would be the case with any number of binomials, and that the law in question was general. But analogy is not enough; we must have rigid proof before we can be warranted in drawing such a conclusion. This we may obtain in the following manner:

Suppose it to be the case, that this law does hold good for the product of a certain number which we will call m, of binomials; let us see whether it be also true, when the number is one greater, or, $m+1$; in other words, when an additional factor is introduced. The successive powers of x will be expressed by

$$x^m,\ x^{m-1},\ x^{m-2},\ x^{m-3},\ \&c.,$$

and the coefficients of these, beginning with x^{m-1}, let us represent respectively by

$$A,\ B,\ C,\ \&c.,$$

A being by supposition equal to the sum of the second terms of the m binomials; B, to the sum of the different products of every two of those terms; C, to the sum of the products of every three of them, and so on. Then Ax^{m-1} will be the seccond term of the product, or that which has one term before it; Bx^{m-2}, the third, or that having two terms before it; Cx^{m-3}, the fourth, which has three terms before it, and so on. As m is undetermined, so must be the number of the terms in the product; we may, however, give a general expression for every one of those terms, by calling it the n^{th} term. This term will, if our rule be, as we suppose, true, have $n-1$ other terms before it. The exponent of x which is supposed gradually to decrease from m in the first term, to zero in the last, will be $m-(n-1)$, or, more simply, $m-n+1$; and the coefficient of that letter will be the sum of the products resulting from the multiplication of every $(n-1)$ of the second terms of the m binomials. Let us call this coefficient M; then the n^{th} term will be represented by Mx^{m-n+1}. Similarly, the next, or $(n+1)^{th}$ term, being that which has n terms before it, will be represented by Nx^{m-n}, N being supposed to stand for the sum of the products of every n of the second terms of the m binomials. Finally, if we designate the last term, or that consisting of the product of all those second terms by U, we have the following expression for the product of m binomial factors.

$$x^m + Ax^{m-1} + Bx^{m-2} + Cx^{m-3} \ldots\ldots Mx^{m-n+1} + Nx^{m-n} \ldots\ldots + U. \qquad \text{(I.)}$$

This product we suppose to obey the laws which we have observed to obtain in the particular cases we examined; and our sole object now is, to see whether, such being the case, those same laws will hold good when the number of factors is increased by one, or made to become $m+1$. Let $x+l$ be the new factor introduced; multiplying the product of m binomials by it, we have for that of $m+1$ binomials

$$\begin{array}{l|l|l|l|l} x^{m+1} + A & x^m + B & x^{m-1} + C & x^{m-2} \ldots\ldots + N & x^{m-n+1} \\ \qquad + l & \quad + lA & \quad + lB & \qquad\qquad + lM & \qquad \ldots\ldots + lU. \end{array}$$

In the first place, the law of the exponents holds good. This is also the case with that of the coefficients. To ascertain this point, however, we must examine them each separately.

1°. The coefficient of the first term is *unity*.

2°. By the supposition, A represents the sum of the second terms of the m binomials, and l is itself the second term of the new binomial introduced; therefore, $A+l$ is *the sum of the second terms* of the $m+1$ binomials. Hence, the coefficient of x in the second term obeys the law laid down.

3°. By the hypothesis, B is equal to the sum of all the products of every two of the second terms of the m binomials; and as A represents the sum of those terms, lA is the sum of the products of each of them by the new factor l; therefore, $B+lA$ expresses *the sum of the products of every two of the second terms* of the $m+1$ binomials. Or the law is true for the coefficient of x in the third term.

4°. C is the sum of the products of every three of the second terms of the m binomials; B is the sum of the products of every two of those terms, whence lB expresses the sum of the products (each consisting of three second terms) resulting from the multiplication of every one of the products (each of two second terms) composing B by the new second term l; therefore, $C+lB$ must represent *the sum of the products of every three of the second terms* of the $m+1$ binomials. Hence, the law holds good for the coefficient of x in the fourth term.

The same would be found to be the case with the coefficients of all the other terms, as we can easily see by referring to that which is a general representative for every term, namely, the $(n+1)^{th}$ term, in which the exponent of x is denoted by $(m+1)-n$, or $m-n+1$, and its coefficient by $N+lM$. By the hypothesis, N is the sum of all the products of every n of the second terms of the m binomials; and M represents the sum of all the products of every $(n-1)$ of those terms; whence lM represents the sum of the products obtained by the multiplication of each of the products composing M by l; therefore, $N+lM$ expresses *the sum of all the products of every n of the second terms* of the $m+1$ binomials, for the multiplication of each of the products of $n-1$ second terms by the additional second term l, renders that product a product of n second terms.

Finally, U being by supposition equal to the product of all the second terms of the m binomials, $U\times l$, or lU, is the product of all the second terms of the $m+1$ binomials: hence, the last term also follows the law laid down.

We have thus proved that if the law of composition which we deduced be true for the product of m binomials, it is equally so for that of $m+1$ binomials; in other words, that if it holds good for the product of any number of binomials, it holds good for that of a number one greater. But we know that it is true for the product of four binomials; it is therefore true for that of $4+1$, or 5; and hence, for that of $5+1$ or 6, $6+1$ or 7, and so on, counting upwards for that of any number of binomials whatsoever. It is therefore general.

This method of demonstration, which is a species of induction, may perhaps not at first appear quite so rigid as others which are employed in algebra; a little reflection will, however, render it perfectly satisfactory. It is one of the highest importance and of frequent application: we may mention another instance of its occurrence, which will be found in the article DIVISION, where it is resorted to for the purpose of proving the divisibility of a^m-b^m by $a-b$.

Since, then, we have established generally the law of composition of the product of any number of binomials, the expression (I), which is formed according to that law, will correctly represent the product of m binomials, $x+a$, $x+b$, $x+c$, $x+d$, &c., the

values of A, B, C; M, N; U remaining as before. Let us suppose now that all the second terms, a, b, c, d, &c. of the m binomials are made equal to one another, that $a = b = c = d$; the product $(x + a)$, $(x + b)$, $(x + c)$, $(x + d)$, &c. becomes in that case the factor $x + a$ repeated m times, or $(x + a)^m$. The changes in the developement of this product, or in the expression (I) itself are more extensive. 1°. The coefficient of the second term, or $a + b + c + d$, &c., becomes $a + a + a + a$, &c., or a repeated as many times as there are letters a, b, c, &c., and is therefore equal to ma; the term itself thus becomes max^{m-1}. 2°. The coefficient of the third term, or $ab + ac + ad$, &c., becomes $a^2 + a^2 + a^2$, &c., or a^2 repeated as many times as there are products ab, ac, ad, &c.; but the number of these products is equal to the number of times that a different two of the m letters a, b, c, d, &c. can be taken; in other words, to the number of combinations of m things taken two at a time; this, as we previously observed, is expressed by $m.\frac{m-1}{2}$, therefore the co-efficient of this term is $m.\frac{m-1}{2}a^2$, and the term itself $m.\frac{m-1}{2}a^2x^{m-2}$. 3°. The co-efficient of the fourth term becomes in a similar manner, a^3 repeated as often as there are combinations of m things taken three at a time, or $m\frac{m-1}{2}.\ \frac{m-2}{3}a^3$; and $m\ \frac{m-1}{2}.\ \frac{m-2}{3}a^3x^{m-3}$ represents the term itself.

The coefficient of the $(n + 1)^{\text{th}}$ term Nx^{m-n}, or that having n terms preceding it, may be ascertained in the same manner. For N represents the sum of all the products of every n of the second terms of the m binomials; but as we now suppose all these second terms to become equal to one another, the sum of the products of every n of them becomes the product of a single n of them, repeated as many times as a different n of them can be taken; in other words as there are combinations of m things taken n at a time. Therefore, N, or the coefficient of the $(n + 1)^{\text{th}}$ term, becomes

$$m\frac{m-1}{2}.\ \frac{m-2}{3}\ \cdots\ \frac{m-n+1}{n}a^n.$$

This expresssion, as we have already observed in a preceding part of this article, may be put under the form of

$$\frac{P(m-n+1)}{Qn}a^n$$

$\frac{P}{Q}$ representing the number of combinations of m things taken $n-1$ at a time; therefore, the $(n + 1)^{\text{th}}$ term will be expressed by

$$\frac{P(m-n+1)}{Qn}a^nx^{m-n}.$$

Finally, the last term of the expression (I), or $abcd$, &c., becomes the product of m equal factors, and is represented therefore by a^m. Collecting together all those terms, we obtain for the product of $x + a$ multiplied m times, or $(x + a)^m$, the following formula:

$$x^m + max^{m-1} + m\frac{m-1}{2}a^2x^{m-2} + m\frac{m-1}{2}.\frac{m-2}{3}a^3x^{m-3}\ \cdots\ + \frac{P(m-n+1)}{Qn}a^nx^{m-n}\ \cdots\ a^m.$$

This formula, then, is the Binomial Theorem; it is the *developement* or *expansion* of $(x + a)^m$, and is a general expression in single terms for any power of a binomial. It enables us to form that power without being obliged to have recourse to the ordinary method of successive multiplication. For instance, suppose that we wished to ascertain the sixth power of $2y + 3z^2$; instead of multiplying that binomial by itself five times, we need only substitute in the above formula $2y$ for x, wherever that letter occurs, $3z^2$ for a, and the number 6 for m; filling up the blanks, if any (which we were obliged to leave so long as m was undetermined), according to the general law of composition, and simplifying by the performance, as far as possible, of the operations indicated, the result will be the power required. We omit the process here; it will form an useful exercise to the student, who may easily verify his result, by comparing it with that obtained according to the ordinary rules of multiplication.

If we now slightly examine this formula, we shall perceive that the law which it obeys, is in every respect of such a simple character, as to be easily remembered; so, that by applying it directly in the formation of a power of a binomial, we may dispense with the intervention of the formula itself. We observe, then,

First, that the number of terms which it contains, is $m + 1$, or greater by unity than that of the binomials multiplied.

Secondly, that with regard to the exponents of the letters x and a,

The exponent of x continually decreases from m in the first term, to zero in the last.

The exponent of a continually increases from zero in the first term, to m in the last.*

Thirdly, that with respect to the coefficients,

The coefficient of the letters ax in the first term is unity; and the coefficient of the same letters in every other term, is successively formed by multiplying the coefficient of those letters in the preceding term by the exponent of x in that term, and dividing by the number of terms which precede the one we are considering.

The first two observations have been already established; the third, which was first remarked by Newton, is of very great practical utility, as it enables us to form at once the expansion of any power, without recurring to the general formula.

The coefficients to which it refers, are evidently entirely numerical, supposing of course, m to have a particular value assigned to it, or to become determined. Of its truth we may easily satisfy ourselves. The coefficient of x^m (or $a^0 x^m$) in the first term is 1, and the exponent of x in that term, m; therefore $\frac{1 \times m}{1}$ or m, is the coefficient of $a\,x^{m-1}$ in the second term. Similarly, $m\ \frac{m-1}{2}$ is the coefficient of $a^2\,x^{m-2}$ in the third term; and $m\ \frac{m-1}{2}.\ \frac{m-2}{3}$ that of $a^3\ x^{m-3}$ in the fourth. The composition of the coefficient of the $(n+1)^{\text{th}}$ term $\frac{P(m-n+1)}{Q\,n}a^n\ x^{m-n}$

* This would give $a^0\ x^m$ for the literal portion of the first term, and $x^0\ a^m$ for that of the last, or as $a^0 = 1$ and $x^0 = 1$, (see Art. ALGEBRA, under the head of *Division*) $1x^m$ or x^m for the first, and $1a^m$ or a^m for the last.

also obeys this law; for the literal portion of the term preceding this, or of the n^{th} term, must be $a^{n-1}\,x^{m-n+1}$, the exponent of a being one less, and that of x one greater than in the $(n+1)^{th}$; and the coefficient of these powers in the n^{th} term must, according to the law of composition we have established, be the number of combinations of m things taken $n-1$ at a time; but this is precisely what $\frac{P}{Q}$ represents, and what we substituted it for; multiplying then the coefficient of the n^{th} term, or $\frac{P}{Q}$ by the exponent of x in that term, or $m-n+1$, and dividing the product by n, the number of terms preceding the $(n+1)^{th}$, or the term we are considering, the result $\frac{P\,(m-n+1)}{Q\,n}$ should be the coefficient of that $(n+1)^{th}$ term; and such as we see is the case. This $(n+1)^{t}$ term $\frac{P\,(m-n+1)\;a^n\,x^{m-n}}{Q\,n}$ is called the *general* term of the devolopement, because by successively giving n every value between 0 and m, it represents each particular term, and whatever we can prove to be true for it must of necessity be true for every term in the developement.

Let us now take as an example the devolopement of $(x+a)^5$.

The first term being $1a^{\circ}\,x^5$ or $1x^5$,

The second becomes $\frac{5\times1}{1}\,a^1x^4$ or $5ax^4$,

The third . . . . $\frac{5\times4}{2}\,a^2x^3$ or $10a^2x^3$,

The fourth . . . $\frac{10\times3}{3}\,a^3x^2$ or $10a^3x^2$,

The fifth . . . . $\frac{10\times2}{4}\,a^4x^1$ or $5a^4x$,

The sixth . . . $\frac{5\times1}{5}\,a^5x^{\circ}$ or a^5.

Here we must stop; we have come to the term in which the exponent of x is zero, and that of a is m, and this according to the law must be the last term. Besides, the expression here ceases for another reason; to continue, it would be necessary to multiply by the exponent of x, but this exponent is zero.

It is evident, that when the exponent of the power to which a binomial is to be raised is an odd number, the developement of that power will contain an even number of terms; and *vice versa*. For the number of terms being always $m+1$, if m be odd, $m+1$ must be even, and if even, $m+1$ must be odd. Thus in the above example, the exponent of the power is 5 in an odd number, and the number of terms is 6, or an even one. We also observe, if we examine the developement of that power, that two terms which are equal distances from its two extremities have always the same coefficient; this is the case with the second and fifth, and with the third and fourth. The reason is this. the coefficient of the third term is equal to the number of combinations of m or 5 things, taken two at a time, or is $\frac{5\times4}{2}$, and the co-efficient of the fourth term to that of the same number of things taken three at a time, or to $\frac{5\times4\times3}{2\times3}$; striking out the common factor 3, the latter becomes $\frac{5\times4}{2}$, or the same as the former. This may be proved generally thus: the coefficient of $a^n\,x^{m-n}$, is according to the general law of composition, equal to the number of combinations of m things taken n at a time, and the coefficient of $a^{m-n}\,x^n$, to that of the same number of things taken $m-n$ at a time; but it is proved in the investigation of the theory of combinations, that these two numbers of combinations are equal, therefore the coefficients of $a^n\,x^{m-n}$ and $a^{m-n}\,x^n$ are equal. Now the term of the developement in which $a^n\,x^{m-n}$ occurs has n terms preceding it; this we can tell from either the exponent of a or x, and the term of $a^{m-n}\,x^n$ has for a similar reason n terms following it, or the former is at the same distance from the beginning that the latter is from the end of the developement; in other words, they are equi-distant from the two extremities. Hence, in the developement of any power of a binomial, coefficients of terms equi-distant from the two extremities, are equal.

Suppose now that we require the developement of $(x-a)^5$, or the fifth power of a binomial whose terms are connected by the negative sign. Proceeding according to the general law laid down,

$$(x-a)^5 = x^5 - 5ax^4 + 10\,a^2x^3 - 10a^3\,x^2 + 5a^4x - a^5$$

Comparing this with the developement of $(x+a)^5$ given above, we find that it differs from that only in having every alternate term, commencing with the second, negative. The reason is evident; every odd power of a negative quantity must be negative, and every even one positive. Thus, $-a\times-a$ is according to the rule of multiplication for negative quantities (see Art. NEGATIVE SIGN), a^2, or the second power of $-a$ is positive; $a^2\times-a$ is $-a^3$, or the third power of $-a$ is negative; and proceeding in this way, we find the different powers of $-a$ in succession to be alternately negative and positive, the odd powers being the former, and the even powers the latter. In the developement then of $(a-x)^5$ the second term must necessarily be negative, for it is composed of

$$5\times(-a)\times x^4 \text{ or } -5\,a\,x^4.$$

The third term contains an even or positive power of a, and is therefore positive; but the fourth contains an odd power, and is therefore negative, and so on. We can therefore easily see the reason why the developement of $(x-a)^m$ should by the substitution of $-a$ for a in the general formula, become

$$x^m - max^{m-1} + m.\frac{m-1}{2}\;a^2\,x^{m-2} - m.\frac{m-1}{2}.\frac{m-2}{3}\;a^3\,x^{m-3}.$$

In other words, why the terms of the developement of any power of a binomial whose second term is negative, should be alternately positive and negative.

In the preceding investigation $(x+a)^m$ stands for $(x+a)\,(x+a)\,(x+a)\,(x+a)$ . . . . &c., or the factor $(x+a)$ repeated m times; consequently m must be a whole positive number, and the formula therefore which we have obtained for the developement of $(x+a)^m$, is therefore only applicable when m is a whole positive number. It has, however, been extended by mathematicians to all cases, whether m be whole or fractional, positive or negative; and the demonstration of this property will be given under the respective heads of FRACTIONAL and NEGATIVE EXPONENTS.

Bipartient, in *Arithmetic*, is a number that divides another into two equal parts without a remainder. Thus 2 is a bipartient to 4, &c.

Biquadrate, in *Algebra*; an obsolete term for the square of the square; in other words, for the fourth power of any given quantity; thus, 16 would be the biquadrate of 2, for $2 \times 2 \times 2 \times 2 = 16$.

Biquadrate Root; the root of a biquadratic power; thus, 2 is the biquadrate root of 16.

Biquadratic Equation; an equation of the fourth degree, or which contains the fourth power of the unknown quantity, as $x^4 + ax^3 + bx^2 + cx + d = 0$.

Bird-Bolt, in *Heraldry*; a small arrow with a blunt head, and often represented in armory, with two, and sometimes three heads rounded; but in that case the number of heads must be noticed.

Biremis; an ancient ship, with two rows of seats for the rowers. A galley.

Bis, in *Music*, in a composition, signifies that the bars included within the same curve are to be sung or played twice successively.

Bismia; an epithet for piano-forte pieces, in which both hands are alternately employed upon the same melody.

Bismuth is a metal called, by artists, *tin glass*, a name obviously derived from the French *étain de glace*. It is found both pure and mineralized by sulphur, oxygen, and arsenic. Native bismuth occurs in the veins of primitive mountains, and is accompanied by ores of lead, silver, and sometimes of cobalt and nickel. It exists in reticulated, lamellar, or amorphous masses; is soft, and of a white colour, occasionally tinged with red. Specific gravity, 9. It is found in many countries,—in France, England, Sweden, Bohemia, and the United States; but its chief locality is at Schneeberg, in Saxony, from whence the supply of bismuth, in commerce, is principally derived. To procure the metal, the ore requires merely to be reduced to convenient fragments, and heated in furnaces, when the bismuth separates from the earthy matter in which it is engaged, and flows out into cast-iron moulds prepared for its reception. Bismuth, when pure, has a reddish-white colour, is harder than lead, and is easily broken under the hammer, by which it may even be reduced to powder. It melts at 470° or 480°, and crystallizes, on cooling, with great regularity, in the form of cubes. When kept in a state of fusion, at a moderate heat, it is covered with an oxide of a greenish-gray or brown colour; at a higher temperature, it enters into a feeble combustion, forming a yellow powder, called *flowers of bismuth*. It combines, by fusion, with a great number of metals, communicating to them brittleness and fusibility. The mixture discovered by Newton, and produced by melting together 8 oz. bismuth, 5 oz. lead, and 3 oz. tin, fuses at 202°. From it are made toy spoons, which melt on being employed to stir very hot tea. A still more fusible compound was invented by Mr. Dalton, composed of 3 parts tin, 5 lead, and 10½ bismuth, which melts at 197°. The addition of a little mercury renders it even more fusible, and fits it to be used as a coating to the inside of glass globes. An alloy of equal parts of tin and bismuth melts at 280°; a less proportion of bismuth adds to the hardness of tin, and hence its use in the formation of pewter. Equal parts of tin, bismuth, and mercury, form the *mosaic gold*, used for various ornamental purposes. One part of bismuth, with 5 of lead, and 3 of tin, forms *plumbers' solder*, a compound of great importance in the arts. Bismuth is also used by letter-founders in their best type-metal, to obtain a sharp and clear face for their letters. Bismuth combines with sulphur, and forms a bluish-gray sulphuret, having a metallic lustre. The same compound is found native in small quantity, and is called, in mineralogy, *bismuth glance*. Nitric acid dissolves bismuth with great readiness. The solution is decomposed on the addition of water, and a white substance, called *magestens of bismuth*, is precipitated, which consists of a hydrated oxide, united to a small proportion of nitric acid. This precipitation, by the addition of water, being a peculiarity of bismuth, serves as a very excellent test of this metal. The magestens of bismuth, from its whiteness, is sometimes employed to improve the complexion, as well as the *pearl powder*, a similar preparation, differing only by the mixture of a little muriatic acid with the nitric acid in effecting the solution of the bismuth. The liberal use of either, however, is highly prejudicial to the skin. They are, besides, liable to be turned black by the vapours evolved from nearly all putrefying substances. The chloride of bismuth, formerly termed *butter of bismuth*, is formed by pouring bismuth, in fine powder, into chlorine gas, or by depriving the muriate of bismuth of its water of crystallization by heat.

Bisti; a species of Persian money, valued at sixteen or eighteen French deniers.

Bistoury, in *Surgery*; a small knife of various forms, according to the purpose for which it is to be used.

Bistre, or **Bister**, in *Painting*; a colour made from the soot of dry wood, of which beech is the best, boiled half an hour in water, of the proportion of a gallon to two pounds of soot; after it has settled, the water is poured from it, and when evaporated to dryness, and made into cakes with gum-water, it is good bistre. Bistre is much used by architects and painters in washing their drawings and sketches. The King of England has a considerable number of fine drawings in bistre by the old masters; and there are also a great quantity of them in the salle d'Apollon, in the Louvre, at Paris.

Bit; a boring instrument, so constructed as to be taken out of the handle, which is called the stock, by means of a spring. Bits are of different kinds, as shell-bits, for boring wood; centre-bits, which form a cylindrical excavation, by turning on an axis or centre; countersink-bits, for widening the upper part of a hole, &c.

Bitumen; the name of a species in *Mineralogy*, the individuals composing which have acquired several distinct names, from their diversity in appearance. This depends chiefly upon their state of aggregation, which forms an uninterrupted series from the perfectly fluid to the solid condition. *Naphtha*, the most fluid variety, is nearly colourless, or of a yellowish tinge, transparent, and emits a peculiar odour. It swims on water, its specific gravity being from 0.71 to 0.84. It burns with a bluish-white flame and thick smoke, and leaves no residue. It consists of carbon, 82.20, and hydrogen, 14.80; and being the only fluid destitute of oxygen, it is used to preserve those new metals in, which were discovered by Sir Humphry Davy. It is found in Persia, in the peninsula of Apcheron, upon the western shore of the Caspian sea, where it rises through a marly

soil in the form of vapour, and being made to flow through earthern tubes, is inflamed for the purpose of assisting in the preparation of food. It is collected by sinking pits several yards in depth, into which the naphtha flows. It is burned in lamps, by the Persians, instead of oil. Near the village of Amiano, in the state of Parma, there exists a spring which yields this substance in sufficient quantity to illuminate the city of Genoa, for which purpose it is employed. With certain vegetable oils, naphtha is said to form a good varnish. The variety *petroleum* is much thicker than naphtha, resembling in consistence common tar. It has a strong, disagreeable odour, and a blackish or reddish-brown colour. During combustion, it emits a thick, black smoke, and leaves a little residue in the form of a black coal. It is more abundant than the first-mentioned variety, from which it does not appear to differ, except in being more inspissated. It occurs, oozing out of rocks, in the vicinity of beds of coal, or floating upon the surface of springs. In the Birman empire, near Rainanghong, is a hill containing coal, into which 520 pits have been sunk for the collection of petroleum; and the annual product of this mine is 400,000 hogsheads. It is used by the inhabitants of that country as a lamp-oil, and when mingled with earth or ashes, as fuel. In the United States, it is found abundantly in Kentucky, Ohio, and New York, where it is known under the name of *Seneca* or *Genese oil*. It is used as a substitute for tar, and as an external application for the remedy of rheumatism and chilblains. *Maltha* is a bitumen, still less fluid than petroleum, from which it differs in no other respect. Its principal locality is at Puy de la Pège, in France, where it renders the soil so viscous, that it adheres strongly to the foot of the traveller. It is also found in Persia, and in the Hartz. It is employed, like tar and pitch, on cables, and in caulking vessels: it is used, as well as the petroleum, to protect iron from rusting, and sometimes forms an ingredient in black sealing-wax. *Elastic bitumen* yields easily to pressure, is flexible and elastic. It emits a strong, bituminous odour, and is about the weight of water. On exposure to the air, it becomes hard, and loses its elasticity. It takes up the traces of crayons in the same manner as the caoutchouc, or Indian rubber, whence it has obtained the name of the *mineral caoutchouc*. It has hitherto been found only in the lead mines of Derbyshire. *Compact bitumen*, or *asphaltum*, is of a shining black colour, solid and brittle, with a conchoidal fracture. Its specific gravity is from 1 to 1.6. Like the former varieties, it burns freely, and leaves but little residue. It is found in Judea, in the Palatinate, in France, in Switzerland, and in large deposits in sandstone in Albania; but no where so largely as in the island of Trinidad, where it forms a lake three miles in circumference, and of a thickness unknown. A gentle heat renders it ductile, and when mixed with grease or common pitch, it is used for painting the bottoms of ships, and is supposed to protect them from the teredo of the West Indian seas. The ancients employed bitumen in the construction of their buildings. The bricks of which the walls of Babylon were built were, according to historians, cemented with hot bitumen, which imparted to them great solidity.

Biventer; an epithet for a muscle that has two bellies, as the biventer cervicis, a muscle of the lower jaw, &c.

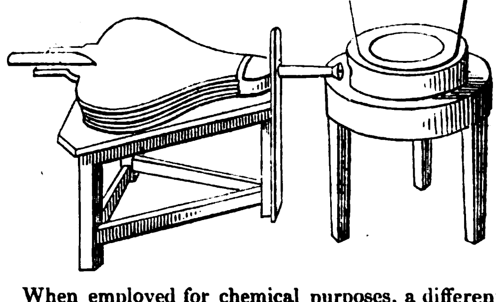
Bivouack (from the German *biwacht*); the name given to the modern system, by which the soldiers in service lie in the open air, without tents, in opposition to the old system of camps and cantonments. They remain dressed, in order to be ready, at a moment's warning, to take their places in order of battle. Tents being laid aside, on the continent of Europe, for the sake of diminishing the baggage of an army, large masses of troops are always obliged to bivouack, even if they are not near the enemy. The soldier, however, is permitted to build himself a hut of straw or branches, if circumstances allow it. Frequent bivouacking is very injurious to the health, and is also a great disadvantage to the countries in which it takes place.

Black, in *Painting;* the darkest of all colours. This colour absorbing all the rays of light and reflecting none, occasions its darkness. There are several species of blacks used in painting, of which the following are the principal:—Frankfort black, of which there are two sorts, one a natural earth inclining to blue; and the other made from the lees of wine burnt, washed, and ground with ivory, bones, or peach-stones. This black is much used by the copperplate printers, for their fine ink to work their engravings. Ivory black is burnt ivory, or bones reduced to powder, and ground in oil or water as required. Spanish black is burnt cork reduced in a similar manner. Harts black is that which remains in the retort after the spirits, volatile salt, and oil, have been extracted from hartshorn. Lamp black is generally prepared in England at the turpentine manufactories, by burning the dregs after the refining of pitch or other resinous matter, in furnaces constructed for the purpose.

Bladder, in *Anatomy;* a membranous bag, serving as a reservoir for some secreted fluid.

Blanket, in *Commerce;* a warm woollen sort of stuff, light and loose woven; chiefly used in bedding. The best blankets are from Witney in Oxfordshire, where the manufacture of them has attained great perfection.

Blast-Furnace; a large conical or quadrangular building, used at iron works for smelting iron-stones and ores.



When employed for chemical purposes, a different sort of apparatus is required. The apparatus best fitted for the laboratory is represented above.

To excite a sudden heat, and to raise it rapidly to the greatest intensity, nothing can be better calculated than this simple furnace. By the ingenious contrivance of dividing a strong blast of air, issuing from a double bellows, and driving it forcibly, first into a small chamber and from thence perpendicularly into a number of converging jets, through the centre of the fire-place, a most intense heat is produced, sufficient to melt down cast-iron, if the fire be properly managed, and the bellows worked with vigour. Coke or cinders, free from clinkers and dust, taken from the common grate, when the coal just ceases to blaze, broken into fragments of the size of a walnut, and mixed with a little charcoal, form an excellent fuel for this furnace; the fire being first kindled by a few lighted cinders and a small quantity of charcoal or chips of wood. This furnace is composed of three parts, all made of black lead. The lower part contains the blast chamber; to this is fitted the body of the furnace which is perforated with blast holes at the bottom; the upper part, or dome inverted, serves to concentrate the heat with more efficacy, and to make it reverberate on the bodies exposed to it; it also protects the eye from the intolerable glare of the fire when the furnace is in full heat; a pair of double bellows is fixed on the stool; the handle, is lengthened to make them work easier. If a very strong blast be wanted, a heavy weight may be secured to the upper board of the bellows.

Blasting; the technical term for splitting any object by means of gunpowder.

Blazoning, or Blazonry, in *Heraldry;* the deciphering of coats of arms, from the German *blasen*, to blow, because the herald blew a trumpet, and called out the arms of a knight, when he entered the lists at a tournament.

Bleaching; a very important chemical process. According to the old system, it was a tedious and unpleasant process, comprising a number of operations, conducted in the following manner: 1, steeping and milling; 2, bucking and boiling; 3, alternate watering and drying; 4, scouring; 5, rubbing with soap and warm water; 6, starching and bluing.

In the first of these operations, the cloth intended to be bleached, disposed in folds, is put into warm water, where it is allowed to remain until the air bubbles, which, after eighteen hours' steeping, begin to arise on the surface, have disappeared; this generally happens, according to the warmth of the weather, in from fifty to seventy hours; if allowed to remain longer, a scum which forms on the surface of the water would precipitate, and the steeping must be discontinued before this occurs. After the steeping, the cloth is taken to the mill, in which by continued agitation with a large quantity of water, all the loose foulness is carried off.

In the bucking and boiling, alkaline leys are employed to remove that particular substance which occasions the brown colour of the cloth. Potash is the alkali mostly employed. The ley is at first put on the cloth only blood warm, it is then drawn off, and poured on at a greater heat. The cloth is next taken into the field and spread out, where it is watered at intervals sufficiently short to keep it constantly wet; for if allowed to dry, while strongly impregnated with alkaline salts, the texture of the cloth would be injured. After this has been attended to, about half a day, dry spots are allowed to appear before the watering is repeated. By this process, the cloth acquires a greater degree of whiteness than before it was taken out, and where the evaporation has been strongest, as on the upper side of the cloth, the colour is whitest. After the cloth has received in the field a tolerably good and uniform colour, as is fit for souring, in which operation it is steeped in sour milk, or in water soured with bran or rye-meal, and used new-milk warm; or what is still better, in water acidulated with sulphuric acid. After being sufficiently soured, which is accomplished in a few hours, the acid is entirely removed by washing in the fulling-mill, and the cloth is then washed by the hand with soft soap and warm water. Coarse cloths are washed more slightly; being rubbed over with soap, they are worked between boards, called rubbing-boards, which effect the purpose by the grooves they contain. The finishing operations of starching and bluing, are conducted in a similar manner to the starching and bluing of the laundry.

The various steepings, boilings, and exposures to the air, to be performed in the process of bleaching above described, consumed much time, and the manufacturer was besides very dependant on the state of the weather; but while the nature of the change produced on the linen was not understood, there appeared but little hope of materially shortening the period employed in completing. The progress of discovery, however, in chemistry, at length threw a ray of light upon the subject, and in a short time the theory of bleaching became better known, and the practice entirely changed. We are indebted to Mr. Hall, of Nottingham, for the first useful employment of the art of chemistry in bleaching. Prior to his time it was a mechanical trade, but that ingenious chemist converted it into a scientific process, which we may now proceed to describe. When a coloured piece of cloth is exposed to the action of oxymuriatic acid, the colour entirely disappears in a longer or shorter period, and the acid, if the quantity of cloth upon which it has been exerted, is sufficient to exhaust it, is reduced to the state of common muriatic acid. It is evident, then, that the colouring matter has lost its property of exhibiting colour by combining with oxygen; and when the cloth thus bleached has been for some time exposed to the air, it becomes yellowish, because part of the oxygen which had combined with the colouring matter flies off. An additional process therefore is necessary, and as it was found that the action of the oxymuriatic acid rendered the substance of the colouring matter soluble in alkaline lixivia, by the employment of such lixivia, a permanent white is obtained. In this new mode of bleaching, the oxymuriatic acid effects, almost immediately, a change, which exposure to the atmosphere requires many weeks to accomplish, and therefore the whole process is prodigiously accelerated. Much complaint was at one time heard, with respect to the injury sustained by the cloths in the new mode of bleaching, and often with justice, as in the infancy of the discovery the want of experience was necessarily attended by the liability to error; and the want of skill, among many who were anxious to adopt it, with a view to commercial advantage, this was often very considerable. But, when properly conducted, it is found to be less injurious to cloth than the old mode, at the same time that it produces a much superior white.

The oxymuriatic acid for the use of the chemist, is

usually obtained by distilling muriatic acid off the the black oxide of manganese; but Berthollet suggested, for the use of the bleacher, the more economical method of obtaining it by the decomposition of muriate of soda, which is effected by diluted sulphuric acid, and the oxide of manganese being added to the mixture, the muriatic acid is produced, and oxygenized at the same time. The following proportions of the ingredients are considered by most to be as the best:

	Parts
Manganese	3
Common salt	8
Sulphuric acid	6
Water	12

The proportion of manganese must be varied according to its quality. The different ingredients should be intimately mixed, and distilled in leaden, earthen, or glass retorts. The distillation should be carried on very slowly, and heat need not be applied till the first disengagement of gas has ceased, after which a sand-bath may be employed, or if the retort be of lead, it may be placed in a vessel of boiling water. The retort must be connected with a receiver, which is designed to collect the muriatic acid that may come over in the first instance, and from this receiver proceeds a tube, the other extremity of which enters a cask of water nearly at the bottom. By this means the gas has to rise through a considerable body of water, which is necessary, as it does not combine very readily with that fluid; its absorption is at the same time promoted by the motion of a circular frame placed in the middle of the cask, and whirled by a handle placed at the top. The intermediate vessel for the retention of the muriatic acid may be dispensed with, by using a long-necked retort which will condense this acid, and it may be caused to run back by giving a suitable inclination to the neck of the retort. By this means the solution of the acid can be made as strong as may be required. It requires to be stronger for coarse than for fine cloth, and for linen than for cotton. The average produce is stated by Berthollet, at 100 quarts for every pound of muriate of soda that has been used. The strength of the bleaching liquor may be tried by dropping a given measure of it into a tincture of cochineal, or a solution of indigo in sulphuric acid, of a certain strength, and by observing the discolouration produced, its strength is known. The cloth is prepared for bleaching by keeping it for some hours in a bath of warm water, and afterwards boiling it in an alkaline ley, containing 20 parts of water and 1 part of potash, rendered caustic by one-third of lime. After this preparation, which opens its pores, removes the soluble part of the colouring matter, and thus prevents an unnecessary waste of oxymuriatic acid, it must be disposed in the bleaching liquor in such a manner that every part may be equally exposed to its action. It is then, alternately, exposed to the action of the bleaching liquor and the alkaline ley, till it is observed to be sufficiently bleached; from four to eight immersions will be required, according to the texture and kind of the cloth, and the colours to be destroyed. Cotton is so much more easily bleached than linen, that when the liquor has little effect on the latter, it will answer perfectly well for the former. From the great volatility of the acid, it becomes desirable to employ close vessels, and one which is extremely simple, and answers the purpose perfectly well, was contrived by Mr. T. L. Kupp, and described by himself in the *Memoirs of the Literary and Philosophical Society of Manchester*. It consists of an oblong deal cistern, made water-tight, and the dimensions of which are adapted to the quantity and size of the cloth intended to be bleached at once. This cistern is covered by a lid, which has a rim that goes within the cistern, and fits it with tolerable accuracy, but may, if thought necessary, be farther secured with pitch. Opposite each other, in a line running lengthwise in the middle of the cistern, and at a distance equal to one-fourth of the length of the cistern, are placed two upright axles of beech-wood or ash, one of whose extremities turns in a wooden step or socket, fixed in the lid, above which they project with a square termination for a handle or a pulley to be slipped upon them. Upon each axle is tightly fastened, by sewing to itself, a piece of strong canvass, one end of which, from the top to the bottom, is left projecting a little. To these pieces of canvass, the ends of the web of calico, &c., to be bleached, may be fastened by wooden skewers, and either axle, on being turned by the handle or winch slipped on the square end at the top, will then have the calico wound upon it, and by putting the winch upon the other axle, the web will be transferred to that axle. The axles are taken out of the cistern to fasten the cloth upon them; when they are replaced, the cistern is filled with bleaching liquor: and as by turning the winch, every part of the web is stretched in succession between the two axles, the whole will be equally bleached, which is an advantage that cannot be obtained by simple immersion. While the cloth is winding upon one of the axles, the ready motion of the other might cause it to become slack, and wind unequally; to prevent this, the axle from which it is drawn, has a small pulley slipped upon its square extremity, and a cord with a moderate weight attached, causes sufficient friction to make the winding regular. When the bleaching liquor is exhausted, it is let off by a spigot and faucet even with the bottom of the cistern. On each axle near the bottom of the cistern is a plain cylinder of thin wood, the diameter of which is at least equal to the diameter of the cloth, when entirely rolled upon either axle; its use is to present a shoulder upon which the cloth may rest, and be prevented from slipping down.

Experience must be the workman's guide, in determining how long the cloth must be worked, and teach him to know the effect which a given quantity of bleaching liquor will produce on a certain number of pieces; but this knowledge, with the use of the test liquor, is acquired without difficulty.

This apparatus may easily be adapted to the bleaching of yarn; for example, if the cylinder we have described as being situated near the bottom of each axle, to prevent the cloth from slipping down, be removed to a situation just under the lid, and be perforated with holes in all directions, and tapes or strings, to support the skeins, be passed through these holes, the skeins hanging down towards the bottom of the cistern, may be revolved as if a web was on the axles, and as the motion communicated to each skein will be equal, no entanglement will occur. Several axles, fitted up in this manner, might be connected by pulleys and bands, and turned by a single winch. To fill the cistern, a short pipe is fas-

tened in the centre, or any other convenient part of the lid; and a pipe from the cask in which the bleaching liquor is made, passes through this pipe to the bottom of the cistern; and by adapting stop-cocks to the tubes, the transfer may be made without allowing any gas to escape.

The apparatus invented by Kupp, and which we have described above, was designed to fulfil several important conditions, all of which it secures. It was designed to be simple and economical in its construction; it was required to confine completely the vapours of the oxymuriatic acid, not only to prevent the loss of allowing it to escape, but to prevent the injurious effects which the breathing of these vapours would inevitably have on the health of the workmen. It must also be observed, that as potash when mixed with the bleaching liquor had been found to prevent the escape of noxious vapours, that alkali had been employed as an essential ingredient in the modes of bleaching previously used. But as the quantity of alkali employed, and which was entirely lost, was equal to about one-fourth of the weight of the salt, it made an addition of 40 per cent. to the expense; and instead of increasing the bleaching power of the liquor, by neutralizing a part of the acid, it actually diminished this power; the advantage therefore gained by a mode of using the pure liquor appears of the first importance.

But experience evinced that something was yet required; the oxymuriatic acid alone had the effect of injuring in some degree the fibres of the cloth, and an ingredient was therefore required which should be cheaper than potash, and less injurious to the power of the liquor: the three earths, lime, barytes, and magnesia, were all found to be capable of being used as substitutes, and lime soon obtained a preference on account of its being the cheapest. The first difficulty that presented itself in the use of this earth, arose out of the slight degree in which it is soluble in water; but it was found that all that was wanting could be accomplished by the mechanical suspension of the lime in water, by means of agitation, as when the oxymuriatic gas entered a close vessel where this was done, the oxymuriate of lime, which is soluble in water, was completely formed, and the clear part of the water which contained it in solution, being drawn off from the undissolved or unsaturated part of the lime, was ready for use as a bleaching liquor. Subsequently, a farther improvement was made, which consists in combining the oxymuriatic acid with dry lime, and dissolving a suitable proportion of this compound to form a bleaching liquor. For this invention a patent was taken out, but the exclusive right was contested in the Court of King's Bench, and decided against the patentee. It is, therefore, open to the public, and the use of the oxymuriate of lime, thus obtained, has long been in general use. It is prepared by introducing the oxymuriatic acid, through leaden tubes, into slaked lime made from chalk. The advantages of using this salt, are, that it is easily preserved or conveyed to a distance; it can be purchased by the bleacher ready prepared, and by the solution of more or less of it, he can at all times immediately obtain his liquor of the strength he requires. The strength of the liquor may be known by the hydrometer, or by trying its effect on diluted sulphate of indigo, in the same manner as the solution of the pure oxymuriatic acid is proved; and the apparatus for exposing the cloth to its action may be the same. Objections have been made to the use of the oxymuriate of lime, on the ground of its injuring the cotton for the reception of some colours, and the oxymuriate of magnesia has been recommended as preferable; but as the latter would be six times the price of the former, the difference of expense amounts to its prohibition, unless greater advantages could be derived from the use of it than have yet appeared. When the cloth has been completely bleached, it is rubbed hard with soft soap and warm water, and washed; it is afterwards steeped in warm water, containing from one-sixteenth to one-hundredth part of sulphuric acid. By this means its whiteness is farther heightened, the odour of the oxymuriatic acid which it retains is diminished, and any small quantity of iron or calcareous earth contained in the cloth is carried off.

In the last stage of the process, the cloth is exposed for a few days to the open air in the field, and frequently watered, to remove every trace of the acids which have been employed. The colours of dyed silk or wool may be removed by the bleaching liquor, and the yellowness which it communicates to them may afterwards be removed by exposing them to the fumes of sulphur; but the practice is too hazardous for commercial use.

The use of the alkaline ley, in bleaching, is to carry off the colouring matter which the action of the oxymuriatic acid has rendered soluble, and hence the necessity for the alternate use of the two agents; but as it appeared probable that a cheaper ley, in which colouring matter was soluble, might be found than that of potash, which is usually employed, and proves very expensive; Dr. Higgens, after various conjectures and experiments on the part of himself and others, found the sulphuret of lime well adapted to the purpose. Sulphur and lime are both cheap articles; they are easily combined, and they do not injure the linen. The sulphuret of lime may be prepared in the following manner for the purpose of bleaching: sulphur, or brimstone, in fine powder, four pounds; lime, well slaked and sifted, twenty pounds; water, sixteen gallons; these are to be well mixed, and boiled for about half an hour in an iron vessel, stirring them briskly from time to time. When the agitation of boiling is over, the solution of the sulphuret of lime clears, and may be drawn off free from the insoluble matter, the quantity of which is considerable. The liquor in this state has nearly the colour of small beer, but is not quite so transparent. Sixteen gallons of fresh are afterwards to be poured upon the insoluble dregs in the boiler, in order to separate the whole of the sulphuret from them. The water last added, is boiled, and the dregs well agitated in it, and when it has become clear, it is drawn off and added to the first liquor: thirty-three gallons more of water are then added, and the liquor is afterwards reduced to the proper state for use. When the cloth has been perfectly cleansed from the weaver's dressing, it is steeped in this liquor from twelve to eighteen hours; it is then taken out, and well washed. When dry, it is to be steeped in the solution of oxymuriate of lime eight or twelve hours, and then washed and dried. These processes are repeated, till the cloth has been six times in each liquor, and it is then usually found to be completely bleached. The saving by the use of the sulphuret of lime is considerable.

The oxymuriatic acid has been extensively em-

ployed by paper manufacturers. It appears at first view, to be well adapted to this branch of trade, as it may be supposed that, whether the rags, or the pulp to which they were reduced, is bleached, the large quantity of water employed would effectually remove every trace of the acid; but the fact is otherwise: large quantities of paper, apparently made according to the best process for bleaching, have been rendered unfit for use; and in all bleached paper, the odour of the oxymuriatic acid is more or less perceptible to the smell, when a parcel of it is fresh opened. Different manufacturers are more or less successful in their use of bleaching; but in those cases where the process is so well conducted that the use of the acid can scarcely be suspected, the care bestowed in washing the pulp causes an additional expense almost equal to that of using a more valuable rag without bleaching. The faults commonly attributed to bleached paper, and which in some degree obviously exist, are, that it is not so proper for writing upon, because the size is injured; that in course of time it weakens the colour of writing ink, and its own whiteness diminishes; that it is apt to break in the folds, and from its little coherence, is easily worn away by friction. It is said even to impair the colour of printing ink, but this has not been fully ascertained. If those who are not very well acquainted with the subject, wish to ascertain whether a parcel of paper is bleached or not, they may hold a piece of it to the fire, till it is thoroughly dried, but not browned; then, while it is yet hot, they may suddenly crumple it up in their hands. If the paper retain any injurious portion of acid, it will by this treatment fall in pieces; but if it break in none of the creases, it may be deemed fit for any purpose.

The oxymuriatic acid has been applied to the bleaching of printed books, and impressions of engravings; but if it have the injurious effects upon paper alluded to above, notwithstanding the superior chance of having the acid extracted in the manufacture, it must be obvious that it can only be applied to those which are of little or no value until restored by its use. The paper of an engraving, however soiled, by smoke, ink, &c., may speedily be restored to a brilliant white, by simply immersing it in the oxymuriatic acid, allowing it to remain a longer or shorter time, according to the strength of the acid solution, or the degree in which it is stained. When a volume is intended to be bleached, the binding must be destroyed to separate it into leaves. The leaves are then placed flat in a leaden cistern, and separated from each other by thin slips of glass or wood: or the leaves may be suspended vertically over narrow slips of wood placed very near each other. In either case the acid must be poured in gently by the sides of the vessel, to prevent disarranging the leaves; and when the full effect has been produced on the paper, it should be drawn off at the bottom, and its place supplied by pure water, which should be changed several times, or until the smell and taste of the acid appears to be wholly removed from the paper. Chaptol observes, that when he had to bleach prints so torn that they exhibited only scraps pasted upon other paper, he was afraid of losing these scraps in the liquid, because the paste became dissolved. In such cases, he enclosed the prints in a cylindrical glass vessel, which he inverted in the water on which he had put the mixture proper for extricating the oxymuriatic acid gas. This vapour, by filling the whole inside of the jar, acted upon the print; extracted the grease and ink-spots, and the fragments remained pasted to the paper.

When for such purposes as bleaching prints, a small quantity of the oxygenated acid is required, without the trouble which would attend obtaining it by distillation, it will suffice to add the black oxide of manganese, or the red oxide of lead, to common muriatic acid diluted with water. The bottle in which the mixture is made should be strong, or its stopper not made very fast, as the elastic vapour which is extricated might otherwise cause an explosion. At the end of two or three hours the acid will have become colourless, and may be used after a little farther dilution. It has an acid taste, because not perfectly saturated with oxygen.

To bleach old printed paper, for the purpose of being worked up again, Pajot des Charmes directs the paper to be boiled for an instant in a solution of caustic soda. That from kelp may be used. Then steep it in soap-suds, and wash it; after which it may be reduced to a pulp. The soap may be omitted, if it be thought proper.

For old written paper to be worked up again: steep it in water acidulated with sulphuric acid, and then wash it well before it is taken to the mill. If the water be heated, it will be more effectual.

To bleach printed paper, without destroying its texture: steep the leaves in a caustic solution of soda, either hot or cold, and then in a solution of soap. Arrange them alternately between cloths, as paper-makers do their sheets of paper when delivered from the form, and subject them to the press. If one operation does not render them sufficiently white, it may be repeated as often as necessary.

To bleach old written paper, without destroying its texture: steep the paper in water acidulated with sulphuric acid, either hot or cold, and then in a solution of oxymuriatic acid; after which immerse it in water, that none of the acid may remain behind. This paper, when pressed and dried, will be fit for use as before.

Bleeding, in *Surgery*, is the artificial extraction of blood from an artery or vein, for medicinal purposes. The operation of cutting an artery is termed arteriotomy; that of opening a vein, is called venesection, or phlebotomy.

The instrument used in this country for bleeding the human subject, is denominated a lancet; though a phleme, or fleam, was formerly employed, and is still very commonly used by farriers in England, and even by the best surgeons in Germany. The lancet, on these occasions, is used single; but where the intention is to puncture numerous small blood-vessels at the same instant, rather than any one considerable vein or branch of an artery, surgeons have recourse to an instrument containing many lancets, which is known by the name of scarificator.

The art of bleeding may be traced back to the remotest antiquity, and seems to have been common among the Egyptians, Assyrians, Scythians, &c., at a time when anatomy had never been cultivated. The Greeks boast that Podalirius, the son of Esculapius, was the first who practised bleeding, soon after the siege of Troy; but the fact itself is related by only one author, who lived too long afterwards to be credited implicitly. It is, therefore, much more likely, that bleeding had been performed previously to the time alluded to. Pliny, indeed, supposes that

physicians first learned this operation from having observed the hippopotamus draw blood by pushing sharp reeds into its body; but this is a very improbable thing, as there is very little analogy between the artificial opening of a vein with a lancet, and the random wounding of an animal by friction against a broken reed.

When we resolve to perform venesection, we must, besides the instruments required for that operation, have in readiness one or two well-rolled blood-letting bandages, or tapes, from four to eight feet in length, and of two fingers' breadth, with pins, or else needles and thread. Those bandages are, by foreigners, reckoned the best, which have narrow straps at their ends.

In general, venesection is practised at the bend of the elbow, or upon the foot; this being previously drawn moderately tight, a bow is tied with a single knot, at the posterior part of the arm. Whether this bandage has been properly applied, we know by the circumstance, that the veins become elevated and tumid, whilst the pulsation of the artery at the wrist is distinctly perceptible.

We then choose a vein in the bend of the elbow, which must be done with caution. The upper is the cephalic vein, and this a beginner ought, if possible, always to choose, as little or no danger is to be apprehended from opening it, but it is very seldom to be seen or felt, and commonly is too small. The median vein is most easily seen and felt; but generally the tendon of the biceps muscle is situated under, or at the side of it, which we must take great care not to puncture.

Blight, in *Agriculture;* a general name for various distempers incident to corn and fruit-trees.

It affects them variously, the whole plant sometimes perishing by it, and sometimes only the leaves and blossoms, which will be scorched and shrivelled up, the rest remaining green and flourishing. Some have supposed that blights are produced by easterly winds, which bring vast quantities of insects' eggs along with them from distant places. These being lodged on the surface of the leaves and flowers of fruit-trees, cause them to shrivel up and perish.

Mr. Knight, however, observes, that blights are produced by a variety of causes; by insects, by an excess of heat or cold, of drought or moisture; for these necessarily derange and destroy the delicate organization of the blossoms; but he believes the common opinion, that they arise from some latent noxious quality in the air, or from lightning, to be totally unfounded. The term blight is very frequently used by the gardener and farmer, he remarks, without any definite idea being annexed to it. If the leaves of their trees be eaten by the caterpillar, or contracted by the aphis; if the blossoms fall from the ravages of insects, or without any apparent cause, the trees are equally blighted; and if an east wind happen to have blown, the insects, or at least their eggs, whatever be their size, are supposed to have been brought by it.

Blind, the; such as are deprived of their sight. The loss of the noblest sense, by means of which man receives an idea of the world that surrounds him, clothed in light and colour, is an event as melancholy as it is frequent. Blindness is different, 1. in its degrees; some persons being partially blind, retaining a slight perception of light, with the power of distinguishing very brilliant colours, and the general outlines of bodies; others being entirely deprived of the faculty of seeing; 2. in its causes: some men are blind from their birth; others have become blind by local diseases of the eyes; for instance, by inflammation, suppuration, cancer of the eye-ball, spots, films, tumours on the cornea (by which its transparency is destroyed), also by closure of the pupil, by a turbid state of the humours, by a debility of the optic nerve, or by general diseases of the body, violent fevers, nervous fevers, plethora, and tendency of the blood to the head, erysipelas in the face, small-pox, scarlet fever, &c., or by excessive exertion of the eyes, by which the optic nerve is enfeebled; for which reason, some classes of mechanics and artists, as blacksmiths, labourers in glass and smelting-houses, watch-makers, &c., not unfrequently lose their sight; and in northern countries, which are covered with snow for a long time, and which dazzle the eyes by the reflection of the sunbeams, as well as in the sandy deserts of Africa, blindness is a frequent complaint. Old age is sometimes accompanied with blindness, occasioned by the drying up of the humours of the eye, or by the opacity of the cornea, the crystalline lens, &c. There are several causes which produce blindness from the birth. Sometimes the eyelids adhere to each other or to the eye-ball itself, or a membrane covers the eyes; sometimes the pupil of the eye is closed, or adheres to the cornea, or is not situated in the right place, so that the rays of light do not fall in the middle of the eye; besides other defects. Those who are born blind have no idea of vision, and are entirely destitute of all the ideas derived from the sense of sight. They cannot, therefore, be sensible of their misfortune in the same degree as those who have lost their sight at a later period. Experience has shown, that those who acquire the power of seeing after being born blind, or having lost their sight in their childhood, form very different ideas of visible objects from other persons.

A young man, whom Chelenden couched for a cataract, at the moment he received sight, imagined that all the objects which he saw were in contact with his eyes: he could not distinguish objects, although of very different forms. Those with which he was already familiar by the touch, he examined with great attention, in order to recognise them another time; but, having too many things to notice at once, he soon forgot all that he had observed. He wondered that those persons whom he loved most were not handsomer than others. Before he received his sight, he had expressed a great desire to obtain this sense. The other senses of persons, who have been blind for a long time, become more exquisite, perhaps, because they are not subject to the distraction produced by the sight of so many objects. The blind, therefore, are often distinguished for a remarkable mental activity, and a wonderful developement of the intellectual powers. Their touch and hearing, particularly, become very acute. Thus it is related of a blind man, who lived at Puisaux, in France, and was a chemist and musician, that he could accurately estimate the proportions of objects, could judge of the distance of fire by the degree of heat, determine the quantity of fluid in vessels by the sound it produced while running from one vessel into another, and the proximity of objects by the effect of the air upon his face. He determined very accurately the weights of bodies and the capacities

of vessels. The celebrated Saunderson, professor of mathematics at Cambridge, lost his sight in his early youth. He invented several processes to facilitate his studies in arithmetic and geometry. His sense of touch was so acute, that he distinguished spurious coins merely by letting them pass through his fingers, though they were so well executed, that even skilful judges were deceived by them.

Blind, Institutions for the. In the case of persons destitute of sight, it is necessary to have recourse to the other senses to supply the want of the eye. If, for instance, we wish to teach them the arts of reading and writing, letters must be prepared, which will be palpable to the touch, and the hand guided until they are able to copy them. If we wish to communicate to them a knowledge of the surface of the earth, globes and maps must be prepared with the divisions, &c., in relief. Knowledge obtained in this way must, of course, be acquired much more slowly than that received by the sight. The senses of touch and of sight differ in this respect, that the of former ascends by degrees from the perception of parts to the perception of the whole, whilst the latter views the whole at a single glance. It is, therefore, evident, that the blind cannot be instructed in the common schools destined for those who see: in the first place, because the means of instruction by the touch are wanting; and secondly, because the progress of the other children would be retarded by the slow apprehension of the blind pupils. For these reasons, and as the blind form no small part of the population of every country, particular institutions have, in many places, been established for their instruction. In Prussia, they amount to more than 13,000 souls. Zeune, in his *Belisar*, has laid down, as a general law, deduced from observation, that the proportion of blind persons decreases from the equator towards the poles. In Egypt, he says, it is as 1 to 100, while in Norway the proportion is 1 to 1000.—The instruction given in the schools for the blind aims, first, at a general cultivation of their intellectual faculties. They are afterwards taught some art which may enable them to provide for their own subsistence. These arts are of two kinds—mechanical employments and music. The instruction of the blind, therefore, embraces three branches—1. mechanical labours; 2. the fine arts; 3. science; because it is impossible to determine, without trial, the peculiar genius of the pupils, whether, for instance, they should be instructed as mechanics, musicians, or mathematicians. The German institutions for the blind, as well as those in Paris, have this comprehensive character, whilst the English aim, more exclusively, to impart instruction in mechanical trades. The first idea of such an institution for blind persons was conceived by Valentin Haüy, brother of the celebrated mineralogist: it was suggested to him by his acquaintance with a blind German lady, the Baroness von Paradis, of Vienna, who visited Paris in 1780, and performed on the organ with general applause. Haüy repeatedly visited this ingenious lady, and was much surprised to find in her apartments several contrivances for the instruction of the blind; for instance, embroidered maps and a pocket printing apparatus, by means of which she corresponded with von Kempelen, in Vienna (the inventor of the chess-player and speaking automaton), and with a learned blind gentleman, named Weissenburg, at Manheim. Haüy compared the high cultivation of these two Germans with the degraded state of the blind in France, where, at the annual fair of St. Ovide, an innkeeper had collected 10 poor blind persons, attired in a ridiculous manner, and decorated with asses' ears, peacocks' tails, and spectacles without glasses, to perform a burlesque concert. Nor did the great institution for the blind, or the hospital of the 300 (commonly called *les quinze-vingt*, founded, in 1260, by St. Louis, after his crusade to Egypt, during which so many soldiers became blind by the ophthalmia, prevailing in that country), present to the philanthropic Haüy a pleasing picture of intellectual cultivation; rather a scene of dulness and moral corruption. He, therefore, resolved to do for the blind in France what the Abbé de l'Epée had done for the deaf and dumb. In 1784, he opened an institution, in which they were instructed, not only in appropriate mechanical employments, as spinning, knitting, making ropes or fringes, and working in pasteboard, but also in music, in reading, writing, ciphering, geography, and the sciences. For this purpose, he invented particular means of instruction, resembling those with which he had become acquainted by his intercourse with the two blind Germans, Paradis and Weissenburg. For instruction in reading, he procured raised letters of metal, from which, also, impressions may be taken on paper: for writing, he used particular writing-cases, in which a frame, with wires to separate the lines, could be fastened upon the paper: for ciphering, there were moveable figures of metal, and ciphering-boards, in which the figures could be fixed: for teaching geography, maps were prepared, upon which mountains, rivers, cities, and the borders of countries, were embroidered in various ways, &c. In the beginning, the Philanthropic Society paid the expenses of 12 blind persons; afterwards, in 1791, the institution was taken under the protection of the state, and united to that for the deaf and dumb; but, as this was found inconvenient, it was, in 1795, separated from the latter, and, in 1801, united to the hospital of the *quinze-vingt*. The mingling of young blind persons here with old soldiers being found very prejudicial to the former, Haüy, full of indignation, went to Petersburg, in 1806, in order to establish a similar institution there. After the restoration, in 1815, the establishment was put upon its original footing, and the physician Dr. Guillié appointed its director.—Next to France, the first institutions for the blind were established in Great Britain, where, however, they are supported only by the contributions of private individuals. In 1790, an institution of this sort was established at Liverpool, in which both males and females are instructed in manual labours, in singing hymns, and playing on the organ. In 1791, a second one was established in Edinburgh, in which the making of baskets and ropes is the principal occupation. Similar institutions have since arisen in other places; one at London, in 1800; also at Dublin, Bristol, and Norwich.—In Germany, the first public institution for the blind was established by the king of Prussia at Berlin, in 1806, when Haüy passed through this city. Zeune was appointed director of it. He invented many instruments more simple than those which had formerly been used, and which answered the purpose very well. Among other things, he brought to great perfection maps and globes, destined for the use of the blind; which, in many parts

of Europe, are used for the instruction of others also, since they present, by means of elevations and depressions of the surface, proportional elevations and pictures, which strike the mind forcibly. In arithmetic, he directed his attention almost exclusively to mental calculations. The first institutions for the blind in Germany, after that in Berlin, were established in Vienna and Prague, both in 1808, and, in the same year, that in Amsterdam, founded by Freemasons. In 1809, the institution in Dresden sprang up—a branch of that in Berlin. In 1810, the institution in Zürich was founded by the auxiliary society. In 1811, a similar establishment was instituted in Copenhagen, after the plan of Professor Brorson, by the *Society of the Chain*, as it is called, (*Verein der Kette*.) After the great war for liberty, from 1813 to 15, when the Egyptian ophthalmia raged so dreadfully among the European armies, several institutions for blind soldiers were established, on Zeune's plan, in Prussia. Their object was to instruct soldiers who had become blind, and unable to exercise their former business, in useful labours. These schools were, at first, intended to continue only till all the soldiers received in them had thoroughly learned some trade: two of them, however, those at Breslau and Konigsberg, have been put upon a permanent footing.

The institution for the blind in Petersburg, which was established by Haüy, but was never in a very prosperous state, seems to have declined greatly, after its founder's return to France, in 1816. The name of its present director is Martin Pilazki. Whether the institution projected at Barcelona, in 1830, has been established, or whether it survived the political storms of that year, or the yellow fever of the succeeding, we do not know. Institutions for the blind are confined almost entirely to Europe, and they appear to be peculiar to Germany, Switzerland, Holland, Denmark, France, England, and Russia. Father Charlevoix, indeed, says, that, in Japan, the records of the empire are committed to the memory of the blind; and Golownin estimates their number in the gigantic city of Jeddo, alone, at 36,000; but neither of them mentions that there is any institution established for them. The director of the institution in Vienna, F. W. Klein, has published a good *Lehrbuch zum Unterrichte der Blinden*, &c. *um sie zu bürgerlicher Brauchbarkeit zu bilden* (Elementary Work for the Instruction of the Blind, &c., to render them useful Citizens).—The first, and as yet the only institution of the kind in America, was commenced in Boston, in the year 1829. In the beginning of that year, an act of incorporation was granted by the legislature of Massachusetts, to several gentlemen, authorizing them to establish the New England Asylum for the Blind, for the purpose of educating blind persons. We understand that this institution is going on prosperously.

Blinds, in operations against fortresses; the name of all preparations which tend to intercept the view of the enemy. There are several species:—1. A fascine placed across the embrasures, to prevent the enemy from observing what passes near the cannon. —2. Blinds before port-holes, are shutters made of strong planks, which are placed before the port-holes, as soon as the guns are discharged, to obstruct the enemy's view.—3. Single and double blinds. The former consist of three strong perpendicular posts, 5 feet in height, between which are planks covered with iron plates on the outside, and thus made shot-proof. This screen is furnished with rollers, to enable the labourers in the trenches to push it before them. The latter consist of large wooden chests, on four block-wheels, which are filled with earth, or bags of sand, and serve likewise in the trenches, &c., to cover the soldiers from the fire of the enemy.—4. Another kind of blinds used to protect the workmen in the trenches, are the chandeliers. Two square beams of timber are placed parallel, and at a distance of six feet, on the ground, and fastened by two cross beams. Upon the ends, perpendicular posts are erected, and the interval is filled up with fascines, at least to a height of five feet.—5. *Blind* is also the name given to coverings placed over the most exposed parts in the approaches or the fortress. These are made of beams, over which hurdles or fascines are spread, that finally receive a sufficiently thick layer of earth as a cover.

Blister, in *Pharmacy*. Blisters are raised on the surface of the body for medicinal purposes, by applying for a number of hours some of the most active of the animal or vegetable stimulants. Of these, by far the most convenient, and that which is most universally employed, is the cantharides, or Spanish fly. These insects are found in Spain, Italy, and the south of Europe; they have a longish body, beautifully brilliant with green and gold. They are gathered by shaking the trees which they frequent, and are killed by the vapour of spirit of wine burnt beneath them, or by the fumes of vinegar, after which they are dried in a stove. In this state they are brought over without farther preparation. For blistering the skin, the cantharides are first finely powdered, and then incorporated with a mixture of wax and resin melted together. The plaster thus made, is spread uniformly upon leather with an iron spatula.

Blocks are pieces of wood in which sheaves or pulleys are placed, for the purpose of forming tackle, purchases, &c., in various operations in naval tactics and architectural constructions. This mechanical power is described in the article **Pulley**. Blocks are single, double, treble, and fourfold, according as the number of sheaves is one, two, three or four. The sheaves are grooved to receive the rope, and have in their centre a brass *bush*, or triangular piece of brass, to receive the *pin* on which they revolve. The sides of the block are called *cheeks*. A *running* block is attached to the object to be moved; a *standing* block is fixed to some permanent support. An example of a block with two pulleys is furnished in the accompanying figure. Blocks also receive different denominations from their shape, purpose, and mode of application. No less than 200 different sorts and sizes are made at Portsmouth for the royal navy, besides which there are various sorts used only in the merchant-ships. The machinery for supplying the royal navy with blocks is the invention of Mr. Brunel. It enables four men, in a given time, to complete the shells of as many blocks as 50 men could do by the old method. Indeed, the block machinery at Portsmouth is justly considered as one of the wonders of the world.

Blockade, is the interception by one belligerent

of all communication with a place occupied by another. National sovereignty confers the right of declaring war, and the right which nations at war have of destroying or capturing each other's subjects or goods, imposes on neutral nations the obligation not to interfere with the exercise of this right within the rules and limits prescribed by the law of nations. In order to render the communication with a place unlawful to a neutral, a blockading or besieging force must be actually present, investing it, and sufficiently powerful to render a communication with it dangerous to a neutral, and expose him to seizure by the blockading or besieging force. A declaration of siege or blockade is an act of sovereignty, but does not require in all cases, a direct declaration by the sovereign authority of the besieging belligerent; for its officers may be invested, either expressly, or by implication, with authority to institute such siege or blockade. It must, however, in order to be lawful and obligatory on neutrals, be declared, or sanctioned, either expressly, or by implication, by the sovereign power. It must also be declared or made public, so that neutrals may have notice of it. If a blockade is instituted by a sufficient authority, and maintained by a sufficient force, a neutral is so far affected by it, that, if he attempts to trade with the place invested, either by carrying goods to it or bringing them away, the property so attempted to be carried to, or from the place, is liable to be seized by the investing party, and, in case of being seized, is forfeited.

BLOCKHOUSE, in *Fortification;* a house made of beams, joined together crosswise, and often doubled, with a covering and loop-holes, large enough for 25 or more men. In addition to this, it is commonly covered with earth, to render it entirely bomb and and fire-proof. It is usually sunk several feet into the ground. Some forts of this kind contain two stories; and they are often fitted up to receive cannon. Blockhouses are generally built in the form of a square or a cross. Their use is to afford a feeble garrison of an important place, which is very much exposed, an opportunity of holding out against the cannonade and assault of the enemy till they are relieved. They also serve for bomb-proof guard-houses, and places of last resort, in the interior of intrenchments, and in the covered passages of fortresses, where the cannon are stationed.

BLOCKING COURSE, in *Architecture;* the course of stones or bricks erected on the upper part of a cornice to form a termination.

BLOMARY, or BLOOMARY, the first forge in an iron-work, through which the metal passes after it is melted out of the ore. See IRON.

BLOOD is the red fluid contained in the blood-vessels of animal bodies. It is found in the mammalia, in birds, in reptiles, and in fishes. In the last two classes of animals, the temperature of the blood is much lower than in the former, for which reason they are distinguished by the name cold-blooded, while the others are termed warm-blooded animals. Insects and worms, instead of red blood, have a fluid of a whitish colour, which is called white blood. In the blood, two different substances are contained, which are separated by coagulation—the serum, a fluid like the white of an egg, and a thick matter, to which the red colour properly belongs, which is much heavier than the former, and is called the coagulum. The last may be divided again into two different parts—into the cruor, or that part of the blood which is intrinsically red, and coagulable, and lymph or fibrine, to which the coagulation of the blood must be ascribed. The fibrine, in young animals, is much whiter than in older and stronger ones. The blood of the latter contains much more azote than that of the former. If the nourishment of animals is changed, we also find an alteration in the constituent parts of their blood. It is also changed by diseases. In animals that are hunted to death, or killed by lightning, the blood does not coagulate. The blood of birds is more highly coloured, and warmer, than that of viviparious animals, and coagulates more easily in the air. That of reptiles and fishes coagulates with difficulty. Aided by magnifying glasses of a strong power, one may observe, in examining the blood of the living animal, or in blood which is newly drawn, that it consists, especially the cruor, of little globular bubbles, the globules of the blood, as they are called, the diameter of which amounts to about the three hundredth part of a line. In blood that has been drawn some time, although this time may be very short, they are not so strongly apparent. They are the effect of the life that pervades the blood. The more robust and healthy an animal is, the more globules are perceived. They show, as it were, the transition from the formless liquid to the original form of the first organized matter. The blood is of the greatest importance to the life of an animal, and may be considered as a source of life. As long as the body is living, the blood is in perpetual motion. When it is taken out of the body, a remarkable change soon follows: it begins to coagulate, and then undergoes, first an acetous, and, after a few days, a putrid fermentation. All the blood takes its origin from the chyle, and deposits, by degrees, the nourishing particles requisite to the preservation and growth of the body, by a multitude of vessels adapted thereto. This is done while it is driven from the heart into the remotest parts of the body, and from thence back. The circulation of the blood is, as it were, the principle and first condition of life. With it, except in cases of fainting, suffocation, &c., life ceases. The heart, the centre of the circulation of the blood, has a twofold motion, of contraction and dilatation, which constantly alternate. With the heart two kinds of vessels are connected—the arteries and the veins. The circulation of the blood proceeds with an astonishing rapidity: did it flow at an equal rate in a straight line, it would run, in the space of one minute, through about 150 feet. This swiftness, however, exists only in the larger vessels near the heart; the farther the blood recedes from the heart, the slower its motion becomes. In a grown-up person, in good health, we may reckon the mass of blood at from 24 to 32 pounds.

BLOOD-VESSELS are the tubes or vessels in which the blood circulates. They are divided into two classes—arteries and veins—which have two points of union or connection; the first in the heart, from which they both originate, and the other in the minute vessels or net-work, in which they terminate. The arteries arise from the heart, and convey the blood to all parts of the body; the veins return it to the heart. The arteries distribute throughout the body a pure red blood, for the purposes of nourishment; while the veins return to the heart a dark-coloured blood, more or less loaded with impurities, and deprived of some of its valuable properties. But

this is not returned again to the body in the same state: for the heart is wisely divided into two portions or sides, a right and left, one of which receives the impure blood from the veins, and sends it to the lungs to be defecated and freshly supplied with oxygen or vital air, while the other receives the pure red blood from the lungs, and circulates it anew through the arteries. The arteries arise from the left ventricle of the heart by one large trunk, nearly an inch in diameter, which is gradually subdivided into smaller ones, as it proceeds towards the limbs, till they terminate, at last, in vessels so small as to be almost invisible, and in a fine net-work of cells, extending through the whole body, in which the blood is poured out, and nutrition or the increase of the body takes place, and from which the residue is taken up by the small veins, to be returned to the heart. The arteries and veins are widely different in their structure, as well as their uses. The former are composed of very strong, firm, elastic coats or membranes, which are four in number. The external covering and the internal lining of the arteries, although belonging to different classes of membranes, are both very thin and soft. The second coat is very thick, tough, and elastic, being that which chiefly gives their peculiar appearance to the arteries. The third is formed of fibres, apparently muscular, arranged in circular rings round the tube of the vessels. It is well known that the pulse of the heart is felt in the arteries alone, although, in the bleeding of a vein, we sometimes see the blood start as if in unison with the beating of the heart. The pulse is produced by the wave or stream of blood, which is driven by the heart through the arteries, distending and slightly elevating them, after which they instantly contract from their elasticity, and thus force the blood into the smaller vessels. The pulse varies in its character with the general state of the health. (See PULSE.) When arteries are cut or wounded, the firmness of their coats prevents their closing, and hence arises the fatal nature of wounds of large vessels, which will remain open till they are tied up, or till death is produced. The veins commence in small capillary tubes in every part of the body, and, by their gradual union, form large trunks, till they at last terminate in two (one ascending from the lower parts of the body, the other descending from the head and arms), which pour their contents into the heart. Their structure is much less firm than that of the arteries. They are very thin and soft, consisting of only two thin coats or membranes. The inner, or lining membrane, is frequently doubled into folds, forming valves, which nearly close the passage in the veins, and thus give very material support to the blood as it is moving up in them towards the heart. These valves are not found in the veins of the bowels, the lungs, or the head. The number of the veins is much greater than that of the arteries, an artery being often accompanied by two veins. They differ also in this, that, while the arteries are deeply seated in the flesh, to guard them from injury, the veins are very frequently superficial, and covered only by the skin. The veins, it is well known, are the vessels commonly opened in blood-letting, although, in cases which render it necessary, a small artery is sometimes divided. There are two portions of the venous system, which do not correspond exactly with our general description; these are the veins of the bowels and of the lungs. The former circulate their blood through the liver before it returns to the heart, and the latter, the pulmonary veins, convey red blood from the lungs to the heart. (For an account of the circulation of the blood, see ANATOMY and HEART.) It should also be mentioned, that the large vein, which brings back the blood from the lower part of the body, receives from the lymphatic and lacteal vessels the chyle from the bowels, which supplies the waste of the blood, and nourishes the body, and the serous and other watery fluids which are taken up by the absorbents in all parts of the body.

BLOTTING PAPER; a species of paper made without size or stiffening, serving to imbibe the wet ink in account books, &c.

BLOWING, in *Medicine;* a method of administering medicines by inflation, or blowing them into the part affected through a tube; powders are thus conveyed into the eye, and sometimes up the nose, for the cure of a polypus.

BLOWING-MACHINES; the larger instruments or contrivances for producing a strong and continued current of air, such as is necessary in smelting-houses, in large smitheries, &c.

BLOW-PIPE is the name applied to an instrument, by means of which the flame of a candle or lamp is made to produce an intense heat, capable of being applied to a variety of useful purposes. Its most simple form is that of a tapering tube, about eight inches in length, and curved nearly at right angles, within two inches of its smaller extremity. At its larger end, it is nearly a quarter of an inch in diameter, and at the smaller, only large enough to admit a common-sized pin. It is made of brass or light iron. In using it, the flame of a lamp or candle is turned aside from its vertical to a horizontal direction by a stream of air impelled upon it, either from the lungs, or from a double bellows. The flame, in its new direction, assumes a conical shape, and consists of two parts, visible by their different colours; the outer being reddish-brown, and the inner blue. The heat at the apex of the inner cone is the most intense, and is equal to that produced in the best furnaces. It is employed by the jeweller and gold smith in the operation of soldering, and by other artists who fabricate small objects in metal; by the glass-blower in making thermometers, barometers, and other glass instruments; by the enameller, and indeed wherever it is required to subject a small body to a strong heat. The common blow-pipe has undergone a variety of improvements in the hands of the chemist, to whose researches it has proved an excellent auxiliary. These consist, principally, in providing its stem with a bowl, or enlargement, where the moisture of the breath may be condensed and detained; in fitting the smaller end so as to receive a variety of little caps, or hollow cones, with orifices of different diameters, so as to be changed according as a flame is required more or less strong; and in rendering the instrument more portable, by constructing it of several pieces, capable of being taken apart and packed up in the space of a pencil-case. With a part, or with the whole of these improvements, it is used by the chemist to make an examination of any doubtful mineral substance, artificial alloy, or pharmaceutical preparation. This he is capable of conducting (with the aid of a charcoal support, and occasionally a little borax) in a moment's time, and with the loss of the smallest imaginable quantity of the substance. To the analyti-

cal chemist its use is indispensable for enabling him to discover the principal ingredients in a substance, previous to his subsequent operations for ascertaining their relative proportion. (For an account of the blow-pipe in which oxygen and hydrogen gases are employed, see OXY-HYDROGEN BLOW-PIPE.

BLUBBER, in *Physiology;* the fat which invests the bodies of all large cetaceous fish, serving to furnish an oil. The blubber is properly the adeps of the animal: it lies immediately under the skin, and over the muscular flesh. In the porpoise it is firm and full of fibres, and invests the body about an inch thick. In the whale its thickness is ordinarily six inches; but about the under lip it is found two or three feet thick. The whole quantity yielded by one of these animals ordinarily amounts to forty or fifty, and sometimes to eighty or more hundred weight.

The use of the blubber to the animal seems to be partly to poise the body, and render it equiponderant to the water; partly to keep off the water at some distance from the blood, the immediate contact whereof would be apt to chill it; and partly also for the same use that clothes serve us, to keep animals warm, by retaining the natural heat of the body. Its use in trade and manufactures is to furnish train-oil, which it does by boiling down. Formerly this was performed entirely ashore in the countries where the whales were caught; but of late the fishers do not always pursue this course, they bring the blubber home, stowed in casks, and then boil it down.

BLUE, in *Painting;* one of the primary colours. This colour, for the use of painters, is variously prepared; the best is ultramarine, which is prepared from lapis lazuli, finely pulverized by ignition, quenched in a strong acid, and subsequently levigated.

BLUE, PRUSSIAN; a colouring matter, of a pure dark-blue colour, a dull fracture, inodorous and insipid, insoluble in water, spirits of wine or ether; it is soluble only by the action of corrosive alkalies. The discovery of this colour was accidently made, in 1704, by Diesbach, a manufacturer of colours, who, with the intention of precipitating colouring matter from cochineal, with which alum and sulphate of iron were dissolved, procured some alkali from the laboratory of Dippel. This alkali, which Dippel had been heating with some animal matter, produced a beautiful blue precipitate. Dippel discovering that the alkali had acquired this power of forming a blue precipitate of iron on account of its mixture with animal oil, soon learned to prepare it in a more simple way, since all animal substances, and even all vegetables, which contain much azote, will give the same result. It is, however, necessary that all the materials should be perfectly pure, since the purification would be too expensive. The addition of alum gives to this blue more body and a brighter colour. This blue substance is a prussiate of iron (52 parts red oxide of iron, and 48 of prussic acid). The alumine added amounts to from 20 to 80 per cent.; but the greater the quantity, the poorer is the quality of the blue.

BLUNDERBUSS, in the *Military Art;* a short species of fire-arm, with a long bore contrived to carry a number of musket or pistol bullets at once. The blunderbuss is proper to do execution in a crowd, or to make good a narrow passage, or door of a house, staircase, or the like.

BOARD; a piece of timber sawed thin, for the purposes of building.

BOARDING, in *Naval Tactics;* the art of approaching the ship of an enemy so near as to admit of the grapplings, which are fixed on the lower yard-arms, at the forecastle, gangways, &c., being thrown into it, for the purpose of securing the vessels together, and of entering her decks with a detachment of armed men.

BOAT; properly, a vessel propelled by oars. In a more extensive sense, the word is applied to other small vessels, which differ in construction and name, according to the services in which they are employed. Thus they are light or strong, sharp or flat bottomed, open or decked, &c., according as they are intended for swiftness or burden, deep or shallow water, &c. The barge is a long, light, narrow boat, employed in harbours, but unfit for sea. The long-boat is the largest boat belonging to a ship, generally furnished with sails, and is employed for cruising short distances, bringing heavy articles on board, &c. The launch is more flat-bottomed than the long-boat, which it has generally superseded. The pinnace resembles a barge, but is smaller. The cutters of a ship are broader and deeper than the barge or pinnace, and are employed in carrying light articles, passengers, &c., on board. Yawls are used for similar purposes, and are smaller than cutters. A gig is a long, narrow boat, used for expedition, and rowed with six or eight oars. The jolly-boat is smaller than a yawl, and is used for going on shore; a merchant-ship seldom has more than two boats, a long-boat and a yawl. A wherry is a light, sharp boat, used in a river or harbour, for transporting passengers. A punt is a flat-bottomed boat, chiefly used for one person to go on shore from small vessels. A skiff is a small boat, like a yawl, used for passing rivers. A moses is a flat-bottomed boat, used in the West Indies for carrying hogsheads from the shore to ships in the roads. A felucca is a large passage-boat, used in the Mediterranean with from 10 to 16 banks of oars. Scow is an American word, signifying a large, flat-bottomed, heavy boat, about 30 feet long, and 12 wide. In some parts of the United States it is called a gondola.

BODY, in *Physics;* a solid, extended, palpable substance; of itself merely passive, and indifferent either to motion or rest; but capable of any sort of motion, and of all figures and forms.

BOIL; to heat a fluid until it bubbles and becomes changed into vapour. If the requisite heat is applied a sufficient time, bubbles continually arise, until the fluid is entirely consumed. A singular circumstance is to be remarked, that the fluid, in open vessels, when it has once begun to boil, receives no increase of heat, even from the hottest fire; the reason is this, that the additional caloric goes to form steam, and ascends with it into the air. The steam itself when formed, may be raised to a much higher degree of temperature. During the period of boiling, the surface of the fluid exhibits a violent undulating motion, and the stratum of air immediately over it is filled with vapour. The noise which accompanies boiling, arises, without doubt, from the displacing of the steam-bubbles, and varies very much with the nature and situation of the vessel. The vaporization of fluids is, very probably, nothing more than a mechanical union of caloric with the fluid. The degree of heat at which different fluids boil is very different. Spirits boil at the lowest temperature; pure water next; at a still higher temperature, the fixed oils. The degree of heat at which a fluid boils is called its

boiling point. This is used as one of the fixed points in the graduation of thermometers. This point is uniform only in case of complete boiling, and under a uniform pressure of the atmosphere. The influence of this pressure appears from experiments. In an exhausted receiver, the heat of the human hand is sufficient to make water boil; while, on the contrary, in Papin's digester, where the confinement prevents evaporation, it may be heated to 300 or 400 degrees without boiling. Under the common pressure of the atmosphere, the boiling point of rain-water is 212° Fah.; that of alcohol, 174°; that of mercury, 660°; that of ether, 98°. From the experiments of Professor Robinson, it appears, that, in a vacuum, all liquids boil about 145° lower than in the open air, under a pressure of 30 inches of mercury; water, therefore, would boil in a vacuum at 67°. Ether may be made to boil at the common temperature, by merely exhausting the air from the vessel in which it is contained.

Boiled, or Boyled Silks; those which have been put while in the balls, into hot water, to make them wind the better.

Boiseau, in *Commerce;* a measure of two bushels and half of a peck, at Bordeaux in France.

Bole; a fossil of a yellow, brown, or red colour, often marked with black dendrites; found in different parts of Bohemia, Silesia, and Styria, also in Lemnos, and at Sienna in Italy. It is made into pipes for smoking, and vessels for cooling water in hot weather. The *terra sigillata* is nothing but bole.

Bollards; large posts set in the ground on each side of a dock. On docking or undocking ships, large blocks are lashed to them, and through these blocks are reeved the transporting hawsers to be brought to the capstans.

Bomb; a large, hollow, iron ball or shell, formerly often made of cannon-metal, and sometimes of an oval form, with a hole in which a wooden fuse is cemented, and with two little handles. Bombs are thrown from mortars. They are filled with powder and combustible matter (which consists of equal parts of sulphur and nitre, mixed with some mealed powder), and are used for setting fire to houses, blowing up magazines, &c. The charge in bombs of 74 pounds contains from 5 to 8 pounds of powder, and 1 pound of the other composition above mentioned. In bombs of 10 pounds, it amounts to 1 pound of powder and from 2 to 3 ounces of the mixture. The fuse, which is hollow, and filled with powder and other inflammable ingredients, sets fire to the charge. The length and the composition of the fuse must be calculated in such a way that the bomb shall burst the moment it arrives at the destined place. Bomb-shells are cast somewhat thicker at the bottom than above, that they may not fall upon the fuse and extinguish the fire; yet they are, at present, often cast of an equal thickness in every part, because it has been found that the fuse remains at the top, notwithstanding. As early as the seventh century, balls filled with burning matter, were thrown from vessels of clay, then from machines called blydes or manges, or with hand-slings made of a small net of iron wire. In 1238, James I. king of Arragon used, at the seige of Valencia, a kind of large rockets, made of four parchment skins, which burst in falling. Afterwards, large iron balls, heated red hot, came in use. In the middle of the fifteenth century, prince Ramini Sigismund Pandulf Malatesta invented mortars and bombs. They consisted, at first, of two hollow hemispheres of metal, filled with powder, and held together by chains. By degrees they received their present shape. An English engineer, Malthus, whom Louis XIII. took into his service, introduced them into France, and used them first (1634) at the sige of Lamotte, in Lorraine. The grenades, which are thrown from howitzers, are easily distinguished from the bombs, which are cast from mortars. The first are used only in the field, the latter in sieges. The Prussian general von Tempelhoff has attempted to bring 10-pound mortars into the field. In order to make a wall bomb-proof, it should be three feet and a half thick.

Bomb-Ketch; a vessel built for the use of mortars at sea, and furnished with all the apparatus necessary for a vigorous bombardment. Bomb-ketches are built remarkably strong, to sustain the violent shock produced by the discharge of the mortars. The modern bomb-vessels generally carry two 10-inch mortars, four 68-pounders, and six 18-pound carronades; and the mortars may be fired at as low an angle as 20 degrees; their principal purpose, at these low angles, being to cover the landing of troops, and protect the coast and harbours. A bomb-ketch is generally from 60 to 70 feet long, from stem to stern, and draws 8 or 9 feet of water, carrying two masts, and is usually of 100 to 150 tons burden. The tender is generally a brig, on board of which the party of artillery remain till their services are required on board the bomb-vessels.

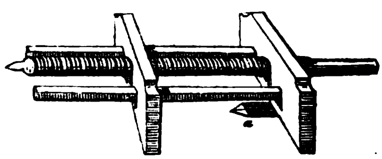
Bone. The bones are the hardest and most solid parts of animals; they constitute the frame, serve as points of attachment to the muscles, and afford support to the softer solids. They are the instruments, as muscles are the organs, of motion. In the mammalia, birds, fish, and reptiles, the whole system of bones united by the vertebral column is called the skeleton. In the fœtus, they are first a vascular gelatinous substance, in different points of which earthy matter is gradually deposited. This process is perceptible towards the end of the second month, and at the time of maturity, the bone is completely formed. After birth, the bones become gradually more solid, and in the temperate zones, reach their perfection in men between the ages fifteen and twenty. From this age till fifty, they change but slightly; after that period they grow thinner, lighter, and more brittle. Those of the two first classes of animals are harder on their exterior than they are internally. Their material, except in the teeth, is nearly the same throughout. Their structure is vascular, and they are traversed by the blood-vessels and the absorbents. They are hardest at the surface, which is formed by a firm membrane, called the periosteum; the internal parts are cellular, containing a substance called marrow. The use of the marrow is to prevent the too great dryness and brittleness of the bones. Chemistry decomposes bone into gelatin, fat, cartilage, and earthy salts. A fresh bone boiled in water, or exposed to the action of an acid, gives out its gelatin; if boiled in water, on cooling the decoction, a jelly is formed which makes a good portable soup. A pound of bone yields twice as much as the same quantity of flesh. The earth of bones is obtained by calcination; that is, by exposing them to a red heat, by which they are deprived of the soft substances. That part of anatomy which treats of the bones is called osteology. See Anatomy.

Bonnet, in *Fortificatian;* an elevation of the parapet in the salient angles of a field intrenchment, or of

a fortification, designed to prevent the infilading of the front of the work, at the end of which it is situated. The bonnet accomplishes, however, only part of this object, and is subject, at least in field intrenchments, to the disadvantage, that the men destined for its defence are too much exposed to be taken in flank by the fire of the enemy, on account of the necessary elevation of the banquette, a fault which cannot occur in the works of a fortress which are well laid out.

Book-Binding; the art of sewing together the sheets of a book, and securing them with a back and strong pasteboard sides, covered with leather, &c. Binding is distinguished from *stitching*, as in the latter the leaves are only sewed, without bands or backs.

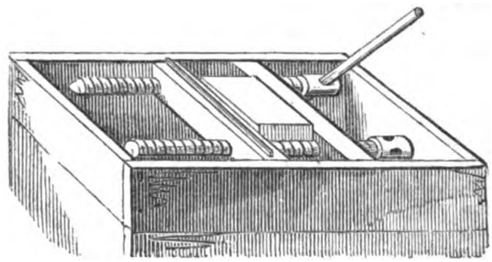
The first operation is, to fold the sheets according to the size of the book, that is, two leaves for folios, four for quartos, eight for octavos, &c., which the workwomen do with a slip of ivory or box, called a folding-stick; in this they are directed by the catchwords and signatures, which are the letters with the numbers annexed to them, at the bottom of the pages. The leaves thus folded, and laid over each other in the order of the signatures, are beaten on a stone with a heavy hammer to make them solid and smooth, and then pressed. Being thus prepared, they are sewed in a sewing-press, upon packthreads or cords, which are called bands, at a proper distance from each other, and in a convenient number; which is done by drawing a thread through the middle of each sheet, and giving it a turn round each band, beginning with the first, and proceeding to the last. The common number of bands is, six in folios, and five in quartos, octavos, &c. Sometimes they use a saw to make places for the bands, which are sunk into the paper, so that the back of the book, when bound, may be smooth, without any appearance of bands. After this the backs are glued, the ends of the backs being opened, and scraped with a knife, for the more convenient fixing of the pasteboards; then the back is turned with a hammer, the book being fixed in a press between boards, called backing boards, in order to make a groove for admitting the pasteboards. The boards being then applied, holes are made for drawing the bands through, the superfluous ends being cut off, and the parts hammered smooth. Then the book is pressed in order for cutting; which is performed by a particular machine called a plough,



to which is fixed a knife, *a*. After this the book is put into a press called the cutting-press, betwixt two boards, the one lying even with the press, for the knife to run upon; the other above it for the knife to cut against.

Now, very much of the success of this operation depends on the form of the knife *a*, and the quality of the steel. If it be very obtuse, then it cuts irregularly, and the steel should be of the best kind of a straw coloured temper. To diminish the danger of breaking, it may be advisable to make the back of the blade of iron.

The cutting frame is shown in the figure beneath.



The book being cut, the pasteboards are squared with a proper pair of iron shears; and it is then ready for sprinkling, gilding, blacking, or marbling the leaves. The colours with which it is sprinkled are usually vermillion, or sap-green; which is done with a brush made with hogs' bristles, holding the brush in one hand, and striking the hair with the other.

A patent was obtained in 1800 by Mr. Palmer, for an improvement in the mode of binding books, particularly account books for merchants. This consists in the addition of a certain metallic chain which is made or applied in the following manner: First provide several small bars of metal, about the thickness of a shilling, or more, according to the size and thickness of the book; the length of each bar being from half an inch to several inches long, in proportion to the strength required in the back of the book. At each end of every bar is made a pivot of different lengths, in proportion to the thickness of two links, which they are to receive. Each link is made in an oval form, and contains two holes, proportioned to the sizes of the pivots; and these links are of the same metal as the hinge, each of them being nearly equal in length to the width of two bars. The links are then rivetted on the pivots, each pivot receiving two of them, and thus holding the hinge together, on the principle of a link-chain or hinge. There are farther, two holes or more of different sizes, as required in each bar of the hinge or chain, by means of which each section of the book is strongly fastened to it; and the hinge so fastened, operates with the back of the book, when bound, so as to occasion the several sections to open freely and admit the ruled lines being written into, without any inconvenience, close to the back.

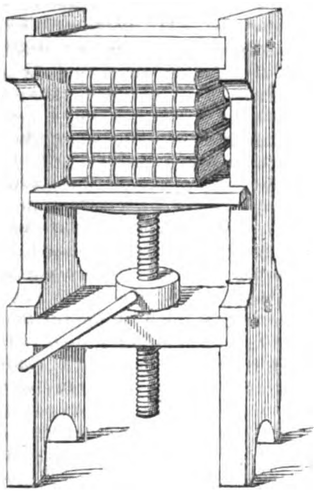
We may now suppose the book prepared for gilding; and, being put tight into the press between two boards, it is scraped with a knife called a scraper; and after that, with another, called a smoother, in order to take out all scratches. Being thus made smooth, it is prepared with a little adhesive mixture: the gold is then laid upon it, and afterwards dried before the fire. When dried, it is burnished off. Blacking the leaves is done with fine antimony rubbed upon them until quite dry, when it is burnished like the gold.

The head-band is now added, which is an ornament of thread or silk, of two or three colours, placed at each extreme of the book, across the leaves, and woven or twisted, sometimes about a single, and sometimes a double piece of rolled paper, or, what is more lasting, of glued paper thread.

When leather is employed, it is first moistened in water, then cut to the size of the book, and the thick-

ness of the edges pared off on a marble stone kept for that purpose. The cover is next coated with paste, made of wheat flour; then stretched over the pasteboard on the outside, and doubled over the edges withinside.

The next step is, to place the book firmly between two boards, to make the cover adhere the stronger to the pasteboards and the back; on the exact performance of which depends a great part of the neatness of the work. The back is then warmed at the fire to soften the glue, and the leather of the back is rubbed on with a folding-stick, to fix it close to the back of the book. It is now placed to dry, and finished. Two blank leaves, on each side, are then to be pasted down to the cover; and, when dry, the leaves are burnished in the press, and the cover rolled on the edges.



The press commonly used for the purpose is shown in the annexed figure. But when a very high relief is required, or great power in the apparatus, then the hydraulic press of Bramah is employed. See HYDROSTATICS.

The cover is now glazed twice with the white of an egg; it is then filletted, plain, or with gold; and at last polished with a polishing iron, passed hot over the glazed cover. If the book be required to be lettered, they sometimes paste pieces of leather for the purpose on the back.

BOOK-KEEPING is a mercantile term used to denote the method of keeping commercial accounts, of all kinds, in such a manner, that a man may thereby know, at any time, the true state of his affairs, with clearness and expedition. Book-keeping is divided into *single*, and *double*, or Italian book-keeping. In the first, the posts of debtor and creditor are separated from each other, and entered in such a way, that each one appears singly; while, in the latter, creditor and debtor are in continual mutual connection, to which end all the posts are entered doubly,—once on the debtor, and once on the creditor side, by which every error or mistake is prevented. This mode of double book-keeping originated in Italy, in the 15th century; yet it had been practised in Spain in the 14th century. The principle of this system is, that all money and articles received become debtors to him from whom they are received, and, on the other hand, all those who receive money or goods in return become debtors to cash or to the goods. The books which the merchant wants are principally, a *waste-book*, in which all his dealings are recorded without particular order; a *journal*, in which the contents of the waste-book are separated every month, and entered on the debtor and creditor sides; and a *ledger*, in which the posts entered in the journal are placed under particular accounts, and from which, every year, the balance is drawn.

BOOMS are long poles employed in extending the sails of a ship. Of these there are several kinds, according to the purposes for which they are intended. Booms, simply so called, are those employed in extending the lower sails when the ship is going large; which is done by putting one end of the boom into the clue of the sail, and the other end to a butt against the side of the ship. These booms are retained in their proper positions by means of ropes called guys.

BOÖTES; a northern constellation, called, also, by the Greeks, *Arctophylax*, and, by the English, *Charles's Wain*. Arcturus was placed, by the ancients, on his breast; by the moderns, on the skirt of his coat. Fable relates that Philomelus, son of Ceres and Jason, having been robbed by his brother Plutus, invented the plough, yoked two bulls to it, and thus supported himself by cultivating the ground. Ceres, to reward his ingenuity, transferred him, with his cattle, under the name of *Boötes*, to the heavens.

BOOTY, in *Military* affairs; the moveables taken from an enemy in war.

BORACIC ACID, uncombined, exists in several small lakes in Tuscany, at Volcano, one of the Lipari islands, and in the hot springs near Sasso, in the Florentine territory, from whose waters it is deposited by natural evaporation. It is easily obtained also from borax, a native salt, composed of this acid and soda, by dissolving it in boiling water, and gradually adding sulphuric acid to disengage the soda: the boracic acid is in this manner set at liberty, and is deposited in crystals on the cooling of the liquid: these, when washed with cold water and dried, are perfectly pure. In this state, it presents the form of brilliant, white, hexagonal scales, soft and greasy to the touch, and having a specific gravity of 1.479. Its taste, when first taken into the mouth, is sourish; afterwards it becomes bitter, and finally leaves a sweetish impression upon the tongue. It is slightly soluble in water, and much more so in alcohol, to which, when burning, it communicates a green colour. It contains 43 per cent. of water, which it parts with, on being heated to redness, when it melts into a transparent glass, and is called *calcined boracic acid*. Boracic acid was discovered by Sir Humphry Davy to be a compound of a peculiar base, which he called *boron*, and oxygen, in the proportion of 8 parts of the former to 16 of the latter. Its principles are separable both by means of galvanism and by the action of potassium. Boron is a tasteless and inodorous substance, in the form of a greenish-brown powder. It is insoluble in water, ether, alcohol, and oils; nor does it fuse when subjected to the strongest heats. By exposure to common air, it gradually becomes oxygenated, and, when heated in oxygen gas, burns vividly, and is converted into boracic acid.—Boracic acid is sometimes employed in the analysis of minerals; and, since its discovery in such abundance in the Italian springs and lakes, it has also been used in the manufacture of borax, being united with soda.—The most important combination formed by boracic acid is that with soda, commonly called *borax*. It is brought into Europe, in an impure state, from the East Indies, under the name of *tincal*, and is understood to occur principally in certain lakes, from whence it is obtained by evaporation. It is also reported to be dug from the earth in Thibet, and to

exist in the mines of Riquintipa and Escapa, in South America. A knowledge of its manufacture was, for a long time, confined to the Venetians and Hollanders. This is now known to consist in boiling carbonate of soda with the calcined tincal, in order to saturate its excess of acid: 12 pounds of carbonate of soda are requisite for every 100 pounds of washed tincal, in the water: the ley is left to cool gradually and crystallize. The French nation manufacture their borax (of which they consume about 25 tons annually) from the boracic acid found in the Italian lakes; in consequence of which the price of this article has fallen in France from five shillings and ten pence the pound, to two shillings and two pence. The process which they adopt is to dissolve 1200 pounds of carbonate of soda in 1000 pounds of water, to which is added, by 20 pounds at a time, 600 pounds of Tuscan boracic acid. This is done in a leaden boiler, of double the capacity requisite to contain the materials, in order to provide for the effervescence which takes place. The heat is kept up for 30 hours, when the clean liquid is drawn off into leaden coolers, a foot in depth, where the first crop of crystals deposits itself in three days. 100 pounds of the best Tuscan boracic acid prdduce about 150 of borax.—Borax appears in crystalline masses of a moderate size, or in distinct hexagonal prisms, terminated by three or six-sided pyramids; is of a white colour, and transparent. It requires 20 parts of cold and 6 of boiling water for its solution. Exposed to heat, it swells up, boils, loses its water of crystallization, and becomes converted into a porous, white, opaque mass, commonly called *calcined borax*. A stronger heat brings it to the form of a vitreous transparent substance, in which state it is known under the name of *glass of borax*. Borax forms one of the best fluxes known. It is used in the analysis of minerals by the blow-pipe, in melting the precious metals, in forming artificial gems, and in soldering.—Another native combination of boracic acid is that with magnesia, known in mineralogy under the name of *boracite*. It is found in small crystals, imbedded in gypsum, near Lunenburg, in Lower Saxony, and at Segebore, in Holstein. Their form is that of a cube, with the edges and four of the solid angles truncated. They are remarkable for their electric properties, becoming, when heated, negatively electrified at their perfect angles, and positively so at their truncated angles.

Borax, see Boracic Acid.

Bordure, or Border, in *Heraldry*, is a partition ıne running all round the inside of the field, of an equal width, taking up one-fifth from the outer edge of the field, and without any shadow.

Boreal; northern.

Boring is a species of circular cutting, in which a cylindrical portion of a substance is gradually removed. When tubes of metal are to be formed, a cast is, in some cases, made in solid metal, and the whole of the bore is produced by the boring machine: in others, the cast is made hollow at first, and the borer is only used to give uniformity and finish to the inside of the tube. In boring cannon, the tool is at rest while the cannon revolves. By this arrangement the bore is formed with more accuracy than by the old method of putting the borer in motion. The tool is kept pressed against the cannon by a regular force. Cylinders of steam-engines are cast hollow, and afterwards bored; but, in this case, the borer revolves, and the cylinder remains at rest. In either case, the axis of the borer and that of the cylindrical material should coincide; for otherwise, if the borer revolve, it will perforate obliquely; if the material revolve, the perforation will be conical. The instruments used are gimblets, augers, centrebits, drills, &c. Drills are made to turn rapidly, either in one direction by means of a lathe-wheel and pulley, or alternately in opposite directions by a spiral cord, which coils and uncoils itself successively upon the drill, and is aided by a weight or fly.—*Boring for water* has been, of late, successfully employed in obtaining a supply without sinking a well. In the progress of the boring, frequent veins of water are passed through, but the operation should be continued until a main spring is struck, which, if from a sufficiently elevated source, will flow up to the surface; otherwise a well must be sunk to the level of the source, and the water must be raised by a pump. To exclude mineral waters, land-springs, &c., the hole is generally cased with a metallic pipe. See Water.

Bossage, in *Architecture*; a projecting stone which is intended to be sculptured. Also rustic work which projects from the plain face of the masonry.

Boudoir; a small room, simply and gracefully fitted up, destined for retirement.

Boutant, in *Architecture*. An arc boutant is an arch or buttress, serving to sustain a vault; and which is itself sustained bv some strong wall, or massive pile.

Bow; the name oı one of the most ancient and universal weapons of offence. It is made of steel, wood, horn, or other elastic substance, which, after being bent by means of a string fastened to its two ends, in returning to its natural state, throws out an arrow with great force. The figure of the bow is nearly the same in all countries, having generally two inflexions, between which, in the place where the arrow is fixed, is a right line. The Grecian bow was nearly in the form of the letter Σ: in drawing it, the hand was brought back to the right breast, and not to the ear. The Scythian bow was distinguished for its remarkable curvature, which was nearly semi-circular; that of the modern Tartars is similar to it. The materials of bows have been different in different countries. The Persians and Indians made them of reeds. The Lycian bows were made of the cornel-tree; those of the Ethiopians, of the palm-tree. That of Pandarus (Il. iv. 104) was made from the horn of a mountain goat, 16 palms in length: the string was an ox-hide thong. The horn of the antelope is still used for the same purpose in the East. The long-bow was the favourite national weapon in England. The battles of Cressy (1346), Poictiers (1356), and Agincourt (1415), were won by this weapon. It was made of yew, ash, &c., of the height of the archer. The arrow being usually half the length of the bow, the *cloth-yard* was only employed by a man six feet high. The arbalist, or cross-bow, was a popular weapon with the Italians, and was introduced into England in the 13th century. The arrows shot from it were called *quarrels*. The *bolt* was used with both kinds of bows. Of the power of the bow, and the distance to which it will carry, some remarkable anecdotes are related. Xenophon mentions an Arcadian whose head was shot through by a Carduchian archer. Stuart mentions a random shot of a Turk, which he found to be 584

yards; and Mr. Strutt saw the Turkish ambassador shoot 480 yards in the old archery ground in London. An old author speaks of a Turkish bow which was known to pierce a steel target, or a piece of brass, two inches thick. In the journal of king Edward VI. it is mentioned, that 100 archers of the king's guard shot at an inch board, and that some of the arrows passed through this and into another board behind it, although the wood was extremely solid and firm. It has been the custom of many savage nations to poison their arrows. This practice is mentioned by Homer and the ancient historians; and we have many similar accounts of modern travellers and navigators from almost every part of the world. Some of these stories are of doubtful authority, but others are well authenticated. Some poison, obtained by Condamine from South American savages, produced instantaneous death in animals inoculated with it. The poisoned arrows used in Guiana are not shot from a bow, but blown through a tube. They are made of the hard substance of the cokarito-tree, and are about a foot long, and of the size of a knitting-kneedle. One end is sharply pointed, and dipped in the poison of woorai: the other is adjusted to the cavity of the reed, from which it is to be blown, by a roll of cotton. The reed is several feet in length. A single effort of the breath carries the arrow 30 or 40 yards.

Bow, in *Music*, is the name of that well known implement by the means of which the tone is produced from viols, violins, and other instruments of that kind. It is made of a thin staff of elastic wood, tapering slightly till it reaches the lower end, to which the hairs (about 80 or 100 horse-hairs) are fastened, and with which the bow is strung. At the upper end is an ornamented piece of wood or ivory, called the *nut*, and fastened with a screw, which serves to regulate the tension of the hairs. It is evident that the size and construction of the bow must correspond with the size of the species of viol instruments from which the tone is to be produced.

Bow, in *Architecture;* a circular end to a church, a room, or building.

Bow Instruments are all the instruments strung with cat-gut or goat-gut, from which the tones are produced by means of the bow. The most usual are the double bass *(violono* or *contrabasso);* the small bass, or *violoncello;* the tenor *(viola di braccio);* and the violin proper *(violino,* from *violon).* In reference to their construction, the several parts are alike: the difference is in the size. See Violin and Quartett.

Bowsprit; a large boom or sprit projecting from the bow of a ship, over the stern, and hence its name.

Braced, in *Heraldry,* is used in speaking of chevronels which are intermingled.

Brachium, the arm, in *Anatomy,* is that part of the upper extremity which intervenes between the joints of the shoulder and elbow.

Bracket, in *Architecture;* a small support against a wall for a figure, lamp, clock, &c., which are susceptible of considerable elegance of design and decoration.

Bracteates; thin coins of gold or silver, with irregular figures on them, stamped upon one surface only, so that the impression appears raised on one side, while the other appears hollow. It seems most probable that these coins, being circulated in great quantities under Otho I., emperor of Germany, when the working of the silver mines of the Hartz afforded the most convenient medium of exchange, were first coined at that place, and spread into other countries, where the Roman money was not known or in circulation. The original form of these coins was borrowed from that of the Byzantian gold ones, which, about that time, lost in thickness what they had gained in extension. Allowance was made, however, for the greater softness of the silver. Gold and copper *bracteates* belong only to a later period. The name *bracteate* itself points to Byzantium (according to Isidore, it is derived from βραχεῖν, to ring). *Bractea* signifies leaf of gold, or other metal. The real name, at the time when they were in circulation, was *denarius, moneta, obolus, panningus.* They are of importance as illustrating history. A very good representation of a rich collection of *bracteates* can be seen in W. G. Becker's *Two Hundred Rare Coins of the Middle Ages* (Dresden, 1813, 4to.) In later times, there have been many bad imitations of these coins, and the study of them is therefore much more difficult. *Bracteated coins,* or *bracteati nummi,* a term used to signify coins or medals covered over with a thin plate of some richer metal. They are usually made of iron, copper, or brass, plated over and edged with gold or silver leaf. Some of them are to be found even among the truly ancient coins. The French call them *fourrées.*

Brails; certain ropes passing through pulleys on the mizzen-mast, and afterwards fastened, in different places, on the hinder edge of the sail, in order to draw it up to the mast, as occasion requires. *Brails* is likewise a name given to all the ropes employed to haul up the bottoms, lower corners, and skirts of the great sails in general. The operation of drawing them together is called *brailing* them up, or hauling them up to the *brails.*

Brain. The brain is a soft substance, partly reddish-gray, and partly whitish, situated in the skull, penetrated by numerous veins, and invested by several membranes. Democritus and Anaxagoras dissected this organ almost 3000 years ago. Haller, Vicq d'Azir, and other anatomists in modern times, have also dissected and investigated it without exhausting the subject. Between the skull and the substance of the brain three membranes are found. The outer one is called the *dura mater.* This is strong, dense, and elastic. It invests and supports the brain. The next which occurs is the *tunica arachnoidea.* This is of a pale white colour, yet in some degree transparent, very thin, and, in a healthy state, exhibits no appearance of vessels. The membrane below this is called the *pia mater.* It covers the whole surface of the brain. It is very vascular, and a great portion of the blood which the brain receives is spread out upon its surface in minute vessels. The brain consists of two principal parts, connected by delicate veins and fibres. The larger portion, the *cerebrum,* occupies, in men, the upper part of the head, and is seven or eight times larger than the other, the *cerebellum,* lying behind and below it. It rests on the bones which form the cavities of the eyes, the bottom of the skull and the *tentorium,* and projects behind over the *cerebellum.* On the whole exterior of the *cerebrum* there are convolutions, resembling the windings of the small intestines. The external reddish substance of the brain is soft and vascular, and is called the *cortical* substance; the internal is white, and is called the *medullary* sub-

stance of the brain. This *medulla* consists of fibres, which are very different in different parts. The *cerebellum* lies below the *cerebrum*, in a peculiar cavity of the skull. By examining the surface, it is seen to be divided into a right and left lobe, by the spinal marrow lying between, but connected at the top and bottom. Like the *cerebrum*, it is surrounded by a vascular membrane, reddish-gray on the outside, and composed of a medullary substance within. In proportion to its size, also, it has a more extensive surface, and more of the vascular membrane, than the *cerebrum*. In a horizontal section of it, we find parallel curved portions of the cortical and the medullary substances alternating with each other. Between the cortical and the medullary substance, there is always found, in the *cerebellum*, a third intermediate yellow substance. All the *medulla* of the *cerebellum* is also united in the middle by a thick cord. Experience teaches that, in the structure of the brain, irregularities are far more uncommon than in other parts of the human body. It is worthy of observation, that every part of the brain is exactly symmetrical with the part opposite. Even those which lie in the middle, and are apparently single (the spinal marrow, for instance) consist, in fact, of two symmetrical portions. The total weight of the human brain is estimated at two or three pounds. It is larger and heavier in proportion to the youth of the subject; and in old age it becomes specifically lighter. In delirious affections, it is sometimes harder and sometimes less solid and softer. The brain is the organ of sensation, and consequently the material representative of the soul, and the noblest organ of the body. See PHRENOLOGY.

BRANCH, in *Anatomy;* a division of a vein, artery, or nerve. All the veins of the body are only branches of the vena cava.

BRANDY. This valuable spirit is produced by the distillation of wines of all kinds, and, properly speaking, by no other fermented liquor whatever. It is prepared in many of the wine countries of Europe, and with particular excellence in many parts of the centre and south of France. The necessary process is extremely simple, being nothing more than a well-regulated distillation of wine without addition, from suitable vessels; but to alter or improve the colour and flavour, various substances are added to the spirit after distillation. Though every wine will give a certain portion of brandy by distillation, some are much preferable to others. In general, the strong heavy wines yield the most spirit, whilst some of the light thin wines furnish no more than about a fifteenth. If the quantity is less than a sixth, it will hardly repay the expense of distillation.

The distilling apparatus is composed of three parts, the *alembic* or boiler, the *capital* which fits on the top of the boiler to receive the spirituous vapour, and the *serpentine* or *worm*, a convoluted pipe fitting to the beak of the alembic, and immersed in a large tub of water to cool the vapour of the spirit, and condense it into a liquor, which flows out at the bottom. See DISTILLATION and ALCOHOL.

BRASS. This very important alloy is a mixture of copper and zinc in various proportions, so intimately united as to form a homogeneous malleable yellow metal, applicable to a vast variety of purposes, and capable of being wrought with the greatest facility.

It is not easy to obtain a perfect union of zinc and copper by mere fusion in open vessels; for at a heat less than is required to melt the copper, the zinc readily takes fire, and much of it burns off before it has time to mix with the other metal, so that the proportion of zinc is constantly lessening by volatilization. Even after both metals are fused, the zinc continues to burn off in uncovered vessels, and at last scarcely any thing but copper would be left. In order, therefore, to combine copper most intimately with zinc, and yet to preserve its malleability, the ingenious process of cementation has been resorted to in the manufacture of brass, which is performed by heating in a covered pot alternate layers of copper in small pieces, with zinc and charcoal, and continuing the fire till the copper is thoroughly impregnated with the zinc.

Zinc being a volatile metal, can only be procured from its ores by sublimation; the process for obtaining it being to heat a mixture of its ore with charcoal in a vessel closed on all sides, except where it admits a tube, the lower end of which dips in water: as soon as the charcoal reduces the oxide, the metal rises in vapour through the tube, and condenses in the water below. A similar reduction takes place in brass-making, only the vapour of the zinc, instead of being conveyed out of the crucible in which it is formed, unites with the copper enclosed in the same vessel, and the whole melts down into brass. A less heat is required in brass-making than that which fuses copper, the zinc being able to penetrate the copper when thoroughly red hot, and melting it down as soon as it becomes brass.

BRAVURA AIR; an air so composed as to enable the singer to show his skill in execution by the addition of embellishments, striking cadences, &c. It is sometimes used for the style of execution.

BREACH; the aperture or passage made in the wall of any fortified place, by the ordnance of the besiegers, for the purpose of entering the fortress. They should be made where there is the least defence, that is, in the front or face of the bastions. In order to divide the resistance of the besieged, breaches are commonly made at once in the faces of the attacked bastions, and in the ravelin. This is effected by battering, and, at such places as the cannon do not reach, by the aid of mines. The breach is called *practicable*, if it is large enough to afford a reasonable hope of success in case of an assault. This is generally considered to be the case if it allows a passage to 14 men abreast. Frequently, however, a breach of much less extent, even of half that width, may be entered.

BREAD. In the earliest antiquity, we find the flour or meal of grain used as food. The inconvenience attending the use of the grain in its natural state, and, perhaps, the accidental observation, that, when bruised, and softened in water, it formed a paste, and, when dried again, a more compact, mealy substance, led, by degrees, to the artificial preparation of bread. Easy as it seems to us, it must have been a long time before it was completely successful. The grain was first bruised between stones, and, from the meal mixed with milk and water, a dry, tough, and indigestible paste was made into balls. This is yet the chief food of the caravans in the deserts of Northern Africa. The Carthaginians, also, ate no bread, and hence were called, in derision, by the Romans, *pultiphagi* (pottage-eaters). After many attempts, or, perhaps, accidentally, it was observed that, by bringing the paste into a state

of fermentation, its tenacity was almost entirely destroyed, and the mass became bread, porous, agreeable to the taste, digestible, and, consequently, healthy. The process formerly pursued may be thus described:—Some old dough, called *leaven*, which, by a peculiar fermentation, has swelled up, become spongy, and acquired an acid and spirituous smell, is kneaded with the new dough, and produces, though in an inferior degree, a similar fermentation in the whole mass. The whole thus becomes spongy; a quantity of air or gas is developed, which, being prevented from escaping by the tenacity of the dough, heaves and swells it, and gives it a porous consistency. This is called the *working* of the dough. In this state, the dough is put into the heated oven, where the air contained in it, and the spirituous substance, are still more expanded by heat, and increase the porosity of the bread, making it materially different from the unbaked dough. In some parts of Sweden, the bread is composed, in part, of the bark of trees, during the winter. In Westphalia, a kind of very coarse, black bread is made, of which the peasants bake one large loaf for the whole week. This is divided for use with small saws. It is called *pumpernickel*, and is sometimes exported. In many parts of Germany, bread is made of grain nearly entire, or but just bruised, which is very coarse, and frequently forms part of the food of the horses. Bread is found wherever civilization has extended. The want of bread has often occasioned public commotions, particularly in Paris and ancient Rome.

The superior nutritious qualities of bread have been doubted; but the question has been set at rest in France, by some chemical researches into the proportional nutriment of various edible substances.

MM. Percy and Vauquelin were appointed to make the experiments on which the solution of these questions rested, and they have published the results in an interesting report on domestic economy. They have ascertained that bread contains 80 nutritive parts in 100; meal 34 in 100; French beans, less; common beans, peas, and lentils, still less; cabbages and turnips, the most aqueous of all the vegetables compared, produce only eight pounds of solid matter in 100 pounds; carrots and spinach produce 14 in the same quantity; whilst 100 pounds of potatoes contain 25 pounds of dry substance. It must be recollected, that the solid parts, when separated from the aqueous or humid parts, may contain a small quantity of extractive or ligneous matter probably unfit for food; and next, that the same substances do not act uniformly on all stomachs, and are relatively more or less nutritious. But as a general result, the learned reporters estimate that one pound of good bread is equal to two pounds and a half or three pounds of potatoes; that 75 pounds of bread and 30 of meat, may be substituted for 300 pounds of potatoes. The other substances bear the following proportions: four parts of cabbage to one of potatoes; three parts of turnips to one of potatoes; two parts of carrots and spinach to one of potatoes; and about three parts and a half of potatoes to one of rice, lentils, beans, French beans, and dry peas.

Where a family grow their own corn, they may be certain of its purity. Its goodness, as a mere article of trade, is measured by the comparative smallness of the quantity of bran which it produces. This, indeed, in family economy, is not of high importance; but if it is wished to make a distinction, then select such wheat as is round and plump, rejecting that which is shrivelled as yielding most bran. Where plump and shrivelled grains are found together in the same binn, they may be separated by simple immersion in water. If the grain be all sound and of equal quality, the smallest grains will still be proportionably the lightest, and will swim whilst the others fall to the bottom; and should a very strict separation be wished for, that may be produced by a judicious application of weak brine, which being gradually poured in, so as to increase the specific gravity of the water, the lighter grains will proportionably rise: this, however, must be stopped in time, otherwise the water will be so impregnated with salt that the whole of the grain will rise to the surface.

If the grain is dried immediately afterwards, it will not receive any damage from the experiment. Should the whole of the harvesting appear at first sight to be damaged, it is not on that account to be absolutely rejected. A gentleman of considerable science and experience has communicated to the Royal Society a process for sweetening musty corn, by simply immersing it in boiling water, and letting it remain till cold. The quantity of water should be double that of the corn to be purified. He has found that the musty quality rarely penetrates through the husk of the wheat, and that in the very worst cases it does not extend beyond the amylaceous matter immediately under the skin. In the hot water all the decayed or rotten grain swims on the surface, so that the remaining wheat is effectually cleaned from all impurities, and without any material loss. The wheat must afterwards be dried and occasionally stirred on the kiln, when it will be found improved to a degree scarcely credible without actual experience.

The first adulteration may be suspected to take place at the mill; but even this, with a little care, may be guarded against by an expense, at first, of about five guineas for a portable mill, which will grind any kind of grain with little comparative trouble.

This species of portable mill was originally constructed for the purpose of supplying the French armies with flour, during their march to Moscow; in the course of which service its merits were fully proved. It was brought from Paris by Sir John Sinclair, and presented by him to the Society of Arts, by whom it is considered one of the most useful machines ever submitted to the notice of that scientific body. With the power of one man it will grind about a bushel of wheat in two hours, and as the labour is not severe, he may grind from four to five bushels per day. It will last for many years, and is not liable to go wrong: the only precautions required in the use of it are, not to turn it above twenty revolutions a minute, as even in that case it would heat (sixteen or seventeen revolutions are as many as is necessary); not to allow the handle to be turned when the mill is empty; and to prevent pieces of iron or hard stone from getting into it. The corn should be dry, or otherwise it would clog the plates, which would make it necessary to take the mill to pieces to clear them. It can easily be attached to any power, either of horses, steam, or water.

People in the flour trade generally knead a small quantity by way of experiment; if good, it immediately forms an adhesive, elastic paste, which will

readily assume any form that may be given to it, without danger of breaking: pure and unadulterated flour may likewise be easily distinguished by other methods. Seize a handful briskly, and squeeze it half a minute; it preserves the form of the cavity of the hand in one piece, although it may be roughly placed on the table. Not so that which contains foreign substances: it breaks in pieces more or less—that mixed with whiting being the most adhesive, but still dividing and falling down in a little time. Flour mixed with ground stones, bones, or plaster of Paris, loses its form at once, and the more bran there may be in it, the sooner will it drop to pieces. It may also be observed, that genuine flour will longer keep the impression even of the cuticle of the skin, than that which is adulterated, the latter very soon throwing up the fine marks.

The admixture of fine pulverised clay in the prime necessary of life, is likewise a practice in many parts of the kingdom; and that in one or two instances, to a very great extent: the industrious adulterators thinking, perhaps, that the white or Cornwall clay might be equal in its nutritious qualities to the German clay, which was thus described some years ago in a German Ephemeris:

"In the lordship of Moscaw, in the Upper Lusatia, a sort of white earth is found, of which the poor, urged thereto no doubt by the calamities of the war in those parts, actually made bread. It is taken out of a hill where they formerly worked saltpetre: when the sun has somewhat warmed this earth, it cracks, and small white globules proceed from it as meal; it does not ferment alone, but only when mixed up with meal. M. Sarlitz, a Saxon gentleman, was pleased to inform us, that he has seen persons who, in a great measure, lived upon it for some time. He assures us, that he procured bread to be made of this earth alone, and of different mixtures of earth and meal, and that he even kept some of this bread by him upwards of six years: he farther says, a Spaniard told him that this earth is also found near Gironne in Catalonia."

As the economical housewife will assiduously avoid the use of alum in her bread, so must she shun all other chemical adulterations, except in cases where the flour to be used is unavoidably musty, or where it is new flour after a wet season, when the bread often comes out of the oven with an unpleasant heaviness about it, which may induce families to give up their own wholesome home-baked, for the produce of some *scientific* baker. The evil spoken of has been obviated by the carbonate of magnesia, but the best remedy is the carbonate of ammonia. If the flour be not very unsound, for 14lbs. of it, use one ounce of carbonate of ammonia, taking particular care to purchase where you can rely upon having it *pure*, as much depends on this. This ounce of carbonate of ammonia should be dissolved in a little warm water, and then put into such farther quantity of water as may be requisite for kneading the dough quite stiff. As this carbonate is volatile, there is no great impropriety in increasing the quantity. It is generally used by bakers and confectioners. In case the flour be very bad, it might be well to make the experiment with 7lbs. of it, as a much larger quantity of the ammonia would be needful; but the very worst of flour may be rendered useable if sufficient of the carbonate of ammonia be introduced. When purchased, the ammonia should be tightly corked up in a phial, in order to prevent the escape of ammoniacal gas, to which it is liable. An ounce of carbonate of ammonia costs less than the same quantity of carbonated soda.

A considerable increase in home-made bread, even equal to one-fifth, may be produced by using bran water for kneading the dough. The proportion is three pounds of bran for every twenty-eight pounds of flour, to be boiled for an hour, and then strained through a hair sieve. The bran need not then be lost, but mixed up with dry food for the poultry yard.

In baking bread at home there are many experiments that may be tried for amusement as well as utility. One mode was formerly actually practised generally in the county of Essex, even so late as the 16th century, and was as follows:—Take peeled turnips; boil them until they are soft; press out the juice and mix them, beaten very fine and small, in their own weight of wheat or flour; add salt dissolved in warm water; knead the whole like other dough, and bake it.

Excellent paste for meat or fruit pies may be made with two-thirds of wheat flour, one-third of the flour of boiled potatoes, and some butter or dripping; the whole being brought to a proper consistence with warm water, and a small quantity of yeast added where lightness is particularly wished for.

This will also make very pleasant cakes for breakfast; and may be made with or without spices, fruit, &c.

Mr. Whately, of Cork, received a gold medal in the year 1813, from the Society for the Encouragement of Arts and Sciences, for a machine for the expeditious rasping of potatoes, and for his experiments in making bread with the farina of them. The bad harvest in 1816 having turned his attention to theoretical improvements, he thus expresses himself on the subject:—"Having by me a considerable quantity of the former, which I had prepared in the year 1813, I began to use it in bread, and find that it has not only very much improved from age, by losing the strong flavour of the raw potatoe, which it retains when recently made, but that it serves to render the flour made from the wheat of last season more palatable. The proportion that I make use of is one-fourth; which has the effect of making the bread lighter, drier, and beyond comparison better than the bread made from the wheaten flour alone of the last crop; and I can safely and strongly recommend its adoption to all those who find bread from new flour heavy, glutinous, and difficult in the preparation. It should be remarked, that the farina I am using was made at a late period of the spring and early in the summer of 1813, after a considerable vegetation had commenced in the potatoes; consequently, it is neither so good nor so profitable as if it had been made before the vegetative process began. The best time for making it is during the first three or four months after the potatoes have been dug from the ground; and although they yield farina to a very late period of the year, it is neither so nutritive in quality, nor so great in quantity, as when it is made at an earlier period. The experiment proves how extremely advantageous it would be for the public, in years when the crop of potatoes is very abundant, to convert a portion of it into farina; which, experience proves, when properly dried, will keep good for almost an indefinite length of time. In such seasons, the farina

which is about one-seventh part of the potatoe, would be produced at about two-pence halfpenny or three-pence per pound.

"It might remain stored up in casks until the seasons called for its use, and become a very great and profitable resource in times of scarcity. Indeed, from the peculiar quality that it possesses, of continuing for years to afford its nutritive properties, not merely uninjured, but really improved by age, I know of no article of food which can, with such advantage be furnished from the bounties of Providence in one season, to administer to the wants of another. It offers such strong inducement in this respect to speculative men, that I shall hope hereafter, in an unproductive year, to see very great relief afforded from it.

"The manufacturer has only to prepare it after the manner of starch at those times when the price indicates a very plentiful supply of potatoes, and to preserve it in his warehouse until a sufficiently tempting price calls it forth, greatly to his own advantage, and to that of the public. Perhaps it is not unreasonable to calculate, that every seventh year would give him the opportunity of doubling or trebling capital thus employed; and I consider it would be well worth the attention of any speculative individual, residing in a country where potatoes are cheap and distant from market, to put this experiment in practice upon a large scale." An account of this process, which is very simple, and an engraving of the machine, may be seen in the volume of the *Transactions of the Society of Arts* for that year.

Breakers; billows which break violently over rocks lying under the surface of the sea. They are readily distinguished by the foam which they produce, and by a peculiar hoarse roaring, very different from that of waves in deep water. When a ship is driven among breakers, it is hardly possible to save her, as every billow that heaves her upward serves to dash her down with additional force.

Breaking Bulk; the act of beginning to unlade a ship, or of discharging the first part of the cargo.

Breakwater. See Cherbourg and Plymouth, in our second division.

Breast. See Chest.

Breast-Plate; a piece of defensive armour, covering the breast, originally made of thongs, cords, leather, &c. (hence *lorica, cuirass*), but afterwards of brass, iron, or other metals. It may be considered as an improvement of the shield or buckler, which was borne on the left arm, and moved so as to protect, successively, all parts of the body. It being perceived that the free use of both hands in the employment of offensive weapons was important, the defensive armour was attached to the body, and received different names from its position, use, &c.; as, for instance, breast-plate, cuisses, greaves. These different species of defensive armour are of little use against fire-arms, and have, therefore, generally fallen into disuse in modern war. *Breast-plate*, in Jewish antiquity, was a folded piece of rich, embroidered stuff, worn by the high-priest. It was set with twelve precious stones, bearing the names of the tribes. It was also called the *breast-plate of judgment*, because it contained the Urim and Thummim.

Breast-Wheel; a water-wheel which receives the water at about half its height, or at the level of its axis. In England, float-boards are employed, which are fitted accurately to the mill-course, so that the water, after acting on the floats by its impulse, is detained in the course, and acts by its weight. In small mills they are often constructed with buckets, and with a part of the circumference fitted to the mill-course.

Breast-Work, in the *Military Art;* every elevation made for protection against the shot of the enemy. Wood and stone are not suitable for breast-works, on account of their liability to splinter. The best are made of earth; in some circumstances, of fascines, dung, gabions, bags of sand, and of wool. The thickness of the work must be in proportion to the artillery of the enemy. In general, it ought not to be less than 10, nor more than 18, or, at most, 24 feet thick. The rule of Cugnot is, that the breast-work should be so high, that nothing but the sky and the tops of trees can be seen within cannon shot from the interior of the intrenchments. If this rule cannot be followed, on account of the height of neighbouring mountains, the interior of the fortification ought to be secured by traverses.

Breath; the air which issues from the lungs, during respiration, through the nose and mouth. This operation is performed without effort, but still it causes a motion in the external air, before the nose and mouth. The air expired is the vehicle of sound and speech. A smaller portion of oxygen, and a larger portion of carbonic acid, is contained in the air which is exhaled, than in that which is inhaled. There are also, aqueous particles in the breath, which are precipitated, by the coldness of the external air, in the form of visible vapour; likewise other substances which owe their origin to secretions in the mouth, nose, windpipe, and lungs. These cause the changes in the breath, which may be known by the smell, like the other qualities of the air. In youth the breath is insipid, and contains acid: it loses these qualities after the age of puberty, and becomes more agreeable. With advancing age, it becomes again unpleasant. A bad breath is often caused by local affections in the nose, the mouth, or the windpipe: viz. by ulcers in the nose, cancerous *polypi*, by discharges from the mouth, by sores on the lungs, or peculiar secretions in them. It is also caused by carious teeth, by impurities in the mouth, and by many kinds of food (viz. horse-radish, onions, and also by flesh, if used to the exclusion of other food), and by fevers. In the last case, it often varies with the character of the disease. The remedy for this complaint must depend on the causes which produce it. Substances of an aromatic kind, which have a strong, rich smell, should be chewed to diminish its offensiveness. Parsley has been found of peculiar use; but it is often impossible to remove this unpleasant disorder. According to the Prussian code, a bad breath furnishes ground for a divorce.

Breathing. The mechanism of the respiratory organs will be discussed under the head of Respiration; but there is a species of breathing of a very marvellous character, of which some account has been given by Dr. Brewster, in his *Natural Magic*, which should be noticed here: One of the most ancient feats of magic was the art of breathing flame, an art which even now excites the astonishment of the vulgar. During the insurrection of the slaves in Sicily, in the second century before Christ, a Syrian named Eanus acquired by his knowledge the rank of their leader. In order to establish his influence over their minds, he pretended to possess miraculous power.

When he wished to inspire his followers with courage, he breathed flames or sparks among them from his mouth, at the same time that he was rousing them by his eloquence. St. Jerome informs us, that the Rabbi Barchochebas, who headed the Jews in their last revolt against Hadrian, made them believe that he was the Messiah, by vomiting flames from his mouth; and at a later period, the Emperor Constantius was thrown into a state of alarm when Valentian informed him, that he had seen one of the body-guards breathing out fire and flames. We are not acquainted with the exact methods by which these effects were produced; but Elorus informs us, that Eunus filled a perforated nut-shell with sulphur and fire, and having concealed it in his mouth, he breathed gently through it while he was speaking. This art is performed more simply by the modern juggler. Having rolled together some flax or hemp, so as to form a ball the size of a walnut, he sets it on fire, and allows it to burn till it is nearly consumed: he then rolls round it while burning some additional flax, and by these means the fire may be retained in it for a considerable time. At the commencement of his exhibition he introduces the ball into his mouth, and while he breathes through it the fire is revived, and a number of burning sparks are projected from his mouth. These sparks are too feeble to do any harm, provided he inhales the air through his nostrils.

Breeching; a rope used to secure the cannon of a ship of war, and prevent them from recoiling too much in the time of battle. It is of sufficient length to allow the muzzle of the cannon to come within the ship's side to be charged.

Breezes, *Sea*, *Land*, and *Mountain*. See Winds and Atmosphere.

Breve; a note of the third degree of length, and formerly of a square figure, as ⊏⊐; but now made of an oval shape, with a line perpendicular to the stave on each of its sides: |○|. The breve, in its simple state, that is, without a dot after it, is equal in duration to one quarter of a large, or to two semibreves, and is then called *imperfect;* but, when dotted, it is equal to three-eighths of a large, or to three semibreves, which being the greatest length it can assume, it is then called *perfect.*

Brevis Cubiti, in *Anatomy;* one of the extensor muscles of the cubitus, arising from the external spine of the humerus.

Brewing, is the art of preparing a vinous liquor from farinaceous seeds, particularly malt. The juices of fruits contain sugar, which is essential to the vinous fermentation. But this does not exist, in any important quantity, in seeds. Instead of it, however, we have starch, and this may combine with water, so as to form sugar. This combination is performed very perfectly by a vital process; that is to say, it takes place only in a living seed, and not in one which is frozen, burned, or otherwise killed. It is known by the name of *germination* or *growing,* and is of familiar occurrence, being what takes place in every seed that is successfully planted. The seeds of wheat, rye, barley, &c., consist principally of starch. If a grain of these is examined, we find near one end of it a small body, which is the rudiment of the future plant, and the microscope shows us that this consists of two parts—the *plumula,* which is destined to ascend through the earth to form the stalk, and the *radicle,* which is to be spread abroad below, and form the root. Whenever a grain of barley, oats, or certain other of the gramineous seeds, is exposed to water, it begins to swell and absorb the moisture; and, at the same time, if the temperature of the air is not too cold, the radicle thrusts itself out at the lower end; the plumula, on the other hand, pushes itself along beneath the husk of the grain to the other end, before it thrusts itself out. There are several curious considerations in regard to this process. The one which concerns us at present is this, that, as the plumula is passing along through the husk, the part of the seed along which it passes becomes changed into the substance known in chemistry by the name of *starch sugar;* that is, when the plumula has passed along one-third of the length of the grain, that third is starch sugar, while the remaining two-thirds are still starch; and so with the rest. The starch sugar seems to be some combination of starch and water. The final cause of the change is undoubtedly the support of the growing plant, sugar being evidently necessary to the growth of plants, as it is always found in their sap, and sometimes, as in the sugar maple, in great quantities. The moment, however, the plumula begins to protrude beyond the end of the grain, the sugar diminishes, as it is consumed by the young stalk; and the substance of the seed is also consumed, though by no means to the same extent, by the growth of the root. To produce this change in seeds, and thereby to fit them for yielding a sweet fluid, when mixed with water, is the business of the maltster; and it is an operation of great delicacy, upon the successful performance of which the success of a manufactory of ale or beer in a great measure depends. The first step in brewing is called *mashing.* It consists in stirring up the malt with a quantity of hot water, which dissolves the starch sugar of the malt, and forms a sweet liquor called *wort,* similar to the must, or sweet juice of the grape, from which wine is made. The manufacture differs, however, in some essential particulars, at this stage of the process, from that of wine; for, if the wort were allowed, as the must is, to ferment without obstruction, it contains so much of the mucilage and starch of the grain, that it would run into the acetous, and from thence into the putrefactive fermentation, and would be *foxed,* as it is technically termed; that is, it would become ill-smelling vinegar instead of beer. To prevent this, it is first boiled. This process renders it stronger, by evaporating a portion of the water; and, farther, it coagulates or curdles the mucilage, which subsides afterwards, and is not again dissolved, thus separating an injurious ingredient. While boiling, a portion of hops is added. One object of this is to give an aromatic, bitter taste to the liquor, which habit has rendered agreeable. The principal object of adding the hops, however, is to check the tendency to the acetous fermentation, which is always far greater, in liquor so compound in its character as beer, than in the simpler liquors, as wine and cider. It is also a common opinion, that hops adds to the intoxicating qualities of the article; and this opinion is probably well founded. One important improvement has been acted on with great success, and which offers a complete safeguard against an accident that often spoils a whole mash.

It is thus described:—the patentee had observed that, in the common way of boiling the wort, the extract is often, if not always, more or less burned; to prevent which, he never suffers fire or flame to

come in contact with the vessel in which the wort is boiled, but performs that process by means of steam, applied on the outside of that vessel. For this purpose he incloses the brewing-vessel in another vessel called the case or jacket, made either of metal or wood, with a sufficient space left between them for the admission of steam from a boiler, by means of tubes, or other convenient communication. In arranging this simple apparatus, attention should be paid to the following particulars: the brewing-vessel must be so well secured in its case, that there may be no way for the steam to escape, but through a valve or cock. The brewing-vessel should rise somewhat higher than the case, as it is not advisable to apply the steam to that vessel higher than the worts within it rise to, as some portions of the hop are apt to adhere to the sides of the vessel, and these, if exposed to a greater heat than the worts, might injure the flavour of the beer. The boiler which supplies the steam should be furnished with a steam-valve, and placed somewhat lower than the brewing-vessel; so that the water produced by the condensation of the steam in the case may be returned to the boiler by a tube. The tube which connects the boiler and the case should be furnished with cocks, that the steam may be excluded or admitted at pleasure. By employing a close brewing-vessel with a safety-valve, the temperature of the wort may be raised above the common boiling temperature of 212°, and a larger portion of extract may thus be obtained from the hop. The flavour of the beer thus brewed is represented as superior to that boiled in the common way, and as being, when properly fermented, more vinous, spirituous, and palatable. After the worts are sufficiently boiled, they are poured out into large shallow cisterns or coolers, till they become cool, and deposit much of the curdled mucilage. They are then allowed to run into a deep tub or vat to ferment. If left to themselves, however, the process would take place very imperfectly, and it is therefore assisted by addition of yeast. The true nature of this substance, notwithstanding much attention and some laborious analyses, is not yet understood. It excites fermentation, however, which continues for a period of time longer or shorter, according to the fancy of the brewer, and is then checked by drawing off the liquor into barrels or hogsheads. In these the fermentation still goes on, but it is now called by brewers *cleansing*. With a view to take advantage of this process, the casks are placed with their bung-holes open, and inclined a little to one side. The scum, as it rises, works out at the bung, and runs over the side, and thus the beer is cleansed from a quantity of mucilage, starch, and other unfermented matters. What does not run out at the bung subsides to the bottom, and constitutes the *lees*. After this cleansing is completed, the clear beer is racked off into barrels, and preserved for use. The scum and lees are collected, and the former constitutes the yeast for the next brewing.—Such is the general history of brewing, whether the product is to be beer, ale, porter, or wash, except that in the latter the cleansing is not necessary.—Even this racking, however, does not remove all the unfermented matter. Some starch and gluten still remain; of course, the liquor soon begins to ferment again in the barrels; but, as these are closely stopped, the carbonic acid gas, or fixed air, cannot escape, but becomes mingled with the beer. Every successive fermentation causes some lees, from which the beer may be racked off, and, by repeated racking, the fermentative matter may be completely removed, and such beers become clear, transparent, and somewhat like the German wines, as, for instance, that commonly called *hock*. But, the disposition to ferment being thus entirely destroyed, they are, like these wines, perfectly still, and acquire no disposition to froth by being bottled. Hence old sound beers may remain in bottles for years without *coming up*, as it is technically called. The object of the brewer is to produce an agreeable beverage, distinguished not so much for absolute strength, or quantity of alcohol, as for colour, flavour, transparency, liveliness, and power of keeping well. Some of these qualities are not compatible with the developement of the greatest quantity of alcohol or ardent spirit, which is the main object of the whiskey-distiller. To effect this purpose, he makes a kind of beer, which is called *wash*. This differs from brewers' beer in some important particulars. In the first place, the grain is not all malted: in England, only a part of it is so; in the United States, generally, none at all. In the next place, it is ground a great deal finer than in brewing. If the brewer were to grind his grist as fine as the distiller, he would run great risk of *setting his mash*, as the phrase is; that is, he would make paste of his grain, and entangle the solution of sugar so effectually, that he could not get it out again. The distiller does not run the same risk, because he does not use such hot water as the brewer, and he can mash and stir his wash a great deal longer without injury, and even with benefit to his liquor. Again, he does not need to boil or add hops to his worts, for he does not care about precipitating the mucilage, or making his beer keep. In the next place, he adds a great deal of yeast, and ferments violently and rapidly, so as to decompose the sugar as quickly as possible, and is quite indifferent whether the worts even become somewhat sourish in the process, as, when sufficiently fermented, the alcohol is removed at once by distillation. If raw grain be ground, mixed with water at a certain heat, and allowed to stand, the change of the starch into starch sugar, or the combination of starch and water, takes place in the same way as in malting. It takes some time, however, and hence the distillers' mashes stand longer than the brewers'. It would seem, therefore, from this, that the malting of grain is not necessary for the making of beer; and, accordingly, this method of proceeding has been recommended by an eminent chemist, one who has paid much attention to this subject, and there can be no doubt that a certain description of small beer may be so made. But the process is not applicable to the finer and more valuable kinds of malt liquors, for reasons which it would require too many details to explain perfectly. Besides the kinds of beer and wash already mentioned, there are others in very common use in America. These are made by mixing honey, molasses or sugar with water, and fermenting with yeast, or some other leaven. Beers made in this way are commonly mingled with some vegetable substance, as ginger, spruce, sarsaparilla, &c., to give them a particular flavour, and are familiar to all by the names of *ginger beer*, *spruce beer*, *sarsaparilla*, &c. &c. The wash of this kind is made from molasses and water, fermented in large vats under ground, by means, not of yeast, but the re-

mains or returns of former fermentations. See ALE, BEER, and PORTER.

BRICK is a sort of artificial stone made principally of argillaceous earth, formed into moulds, dried in the sun, and baked by burning. The use of unburnt bricks is of great antiquity. They are found in the Roman and Grecian monuments, and even in the ruins of Egypt and Babylon. They were dried in the sun instead of being burnt, and mixed with chopped straw, to give them tenacity. On account of the extreme heat and dryness of the climate, they acquired great hardness, and have lasted for several thousand years; but they are unsuitable for more northern latitudes. The most common bricks, among the Romans were 17 inches long, and 11 broad; and, in later periods, they were burned.

BRICK-MAKING has, of late years, furnished a very considerable branch of trade around the metropolis, not only very productive to the land-owners, but it has produced an extensive help to the revenue of the country; yet, much of the brick now in use will hardly wear out a twenty-one years' lease. That there must be something radically wrong in the present system of manufacturing the brick earth, is very evident, as we have the same means of procuring brick earth equally fit for the purpose as formerly. With this impression, we think it may be beneficial to furnish our readers with the theory and practice of brick-making, as drawn up some time since by Mr. James Malcom.

He observes, that the manufacture of them is of the utmost importance to the community, inasmuch as the value and comfort of our dwellings must depend in a great measure on the quality of the materials with which they are constructed; and bricks form no inconsiderable part of them. I say, it is material to us, because, if the bricks with which our houses are now almost uniformly built, are in quality defective, and if the timber be of a similar description, we ought not to place much dependance on the solidity of the edifice.

The soil on the Surrey side of London is only calculated for certain sorts of bricks, and these, it must be confessed, are inferior to those made in Middlesex. We have neither depth nor that pure argillaceous substance, which is so essential to form the perfect brick; we have either too much silex, or, to speak the common language, too much flinty sand; and the stones are too abundant, large, and too near the surface, which causes the bricks to vitrify, and thereby their colour and quality is injured; or we have a portion of calcareous matter, which causes the bricks, after being taken from the clamps, insensibly to moulder away by exposure to the air or moisture; and were it as argillaceous as in Camberwell and Dulwich parishes, it is to that extreme, as to be impossible to be moulded without the assistance of some adventitious combinations. What those combinations were, which form the several varieties of bricks manufactured in the county, together with some cursory remarks, will form the subject of this essay.

At Kennington, at Walworth, at Camberwell, and in Battersea parishes, we have manufactories of bricks to a much greater extent probably, than all the rest of the county united. In analyzing the earth which has been generally used, I followed the plan of the learned Bishop of Landaff. Eight ounces of earth taken out of the pit as they were digging (Mr. Fentiman's) and moulding it into an oblong square, I placed on the hob of a Bath stove in my study, where a constant fire was kept for seven days. I then weighed it, and found it had lost one ounce and three quarters. I did the same by that at Walworth, and during the same time it lost nearly two ounces; that at Camberwell lost in the same time three ounces four pennyweights; that at Battersea, two ounces six pennyweights. In the solution of these earths, after having exposed them to the muriatic and the acetous acid, it was evident that, besides a large portion of pure argil which the earth at Camberwell contained, there were not less than eighteeen parts in one hundred of iron, a small portion of silex, and about six parts in one hundred of calcareous earth: and it will be seen, that the quantity of water which the clay and the calcareous earth held, was considerable; from this I infer, that, although the colour of the bricks, and the difficulty and consequent expense in moulding the latter was greatly against the manufacture, yet, as to the materials, they were far superior to the others in an essential property, I mean durability. Those at Kennington and Walworth were nearly similar in their products, the latter possessing the most argil; and those at Battersea still more; the earth therefore imbibing more moisture, consequently loses more in burning.

The moulds used in making every sort of brick for building purposes are ten inches in length, and five in breadth; and the bricks when burned usually measure nine inches in length, and four and one-half in breadth, so that the clamp shrinks about one inch in ten. But the degree of contraction (as we have before seen) which clay undergoes in being burned, does not absolutely depend upon the purity of the clay; for as some clay imbibes more moisture than others, if that which imbibes the most is not exposed a much longer time to the frost to divide and separate its particles, and to the heat of the sun to exhale its moisture, than that which imbibes less and is a shorter time exposed, it follows, that while the one will be reduced one inch, the other may lose two or more. Again, the heat of the kiln or clamp, and the situation of bricks as to heat will vary the diminution of the subject to be burnt. It is of consequence, therefore, in the making of sound hard bricks, that the clay should be dug two or three years before it is used, in order that it may be pulverised; and the oftener it is turned and incorporated, the better will be the bricks. The earth should have sufficient time to mellow, ferment or digest, which will render it more apt and fit to temper; and this operation of treading and tempering ought to be performed more than double the usual time, because the goodness of the bricks wholly depend upon the well performance of its first preparation, since the earth in itself, before it is wrought, is generally brittle, full of extraneous matter, which requires to be removed, and as it were without unity and stability; but by adding small quantities of water by degrees to it, and working and incorporating it together, the several parts of it are opened, and by being thus exposed to the atmosphere a tough and gluey substance is formed, which, without such tempering, treading, and beating, could not have been produced. I can only compare this preparation of the soil to that of making bread. When there is a due quantity of water put to the flour, and well wrought up together, such bread comes not only

smooth and firm, without having eyes or being subject to crumbling, but it eats sweeter and mellower, and becomes easier of digestion, affording far better nourishment than such as is over-watered, heavy, and not sufficiently tempered; provided the other operations, which belong to the making of good bread, such as baking, &c. be properly performed.

Bricks thus tempered become solid, smooth, hard, and durable; and one brick thus made takes up nearly as much earth as a brick and a half made in the common way; but these are light, full of cracks, and spongy, owing to the want of due working and management; and the mixing of ashes, which is now the uniform practice about London, and light sandy earth which is usually practised in the country, to make them work easy and with greater dispatch, serves also to save coals or wood in the burning of them. See *Malcolm's Survey*.

The excellency of bricks consists chiefly in the first and last operation; for bricks made of good earth and well tempered, become solid and ponderous, and therefore will take up a longer time in drying and burning than our common bricks seem to require. It is also to be observed, that the well drying of bricks before they are burned, prevents cracking and crumbling in their burning; for when the bricks are too wet, the parts are prevented from adhering together. The best way of ordering the fire is to make it gentle at first, and increase it by degrees as the bricks grow harder. If those several operations were properly and duly attended to, we should not see such immense waste, and so great a profusion of unburnt and half-burnt bricks, called place bricks, as we constantly find on the outsides of our modern clamps. For want of due precaution the fire never reaches them in an equable degree, and therefore they ought to be totally disregarded and laid aside; but modern ingenuity, and the tricks of the builders, have found out a mode of using them, less objectionable to be sure than if they were consigned to the outside walls, though properly they are not fit to be used any where. It is necessary that the public should be informed, that these place bricks are now made use of in the inside walls of houses of every denomination, from the hut to the palace; and that they are soft, subject to very quick decay, and wherever wet can at all get to them, they moulder away with great rapidity; nor is this the only objection to them; they are subject to be acted upon by every change of the weather, so that the walls become damp, and the plastering discoloured, causing the bond timbers and plates to rot; and for want of equal solidity with the external bricks, the walls crack, and the timbers swag, because the bearing on them cannot be then any where equally poised.

The dampness which so often affects the inside walls, is attempted to be palliated or removed by the introduction of what is called battening, whereby an opening or cavity is left between the brick-work or plastering; but whoever has attentively observed the result of this invention, which in very many instances has fallen to my lot to notice, will see that the damp arising from these bricks engenders mould, and is visible on the frame of the wood used in the battening; this mould is, no doubt, the secondary cause of the dry-rot, since the origin must be in the bricks themselves.

That this is the case, may be deduced from this fact, that wherever a quantity of those bricks is heaped up together for any length of time, they will upon separation be found to have their bases covered with a fine white net-work, especially those which are nearest the bottom. Hard burnt, sound bricks never have this net-work grow upon them, let them lay as long as they may in any situation. This net-work then is the plantulæ of mould. The origin and increase of mould is nearly in proportion to the heat of the atmosphere; its appearance and vegetation are never more sudden than during the summer, and the reason seems to be, that the heat of the weather necessarily draws out the redundant moisture from the bricks for want of a due circulation of air. This moisture attaches itself to the outside of the bricks, and there remains, the heat not being sufficient to dry it up, but enough perhaps to produce a degree of warmth; it enters into a slow but certain process of fermentation; and, passing through a state of acidity to putrefaction, is of itself sufficient to engender mould. Sometimes it is very long before mould is produced on particular substances, either from the absence of the seed, or the substance not being well adapted for its vegetation; while in others, the seed has been known to vegetate in three hours. The mould, from being first white, turns yellowish, and at last blackens. As it approaches a state of maturity, a kind of black dust falls from it, which is the seed of the plantulæ; a quantity of this dust constitutes the powder, which blackens the hand when touched. As this dust and seed is so fine and infinite, it spreads with a rapidity equal to the state and condition of the substances which may be fit to receive it, and hence may attack a whole building, and becomes the means of endangering and eventually destroying the most superb edifice.

Another fact will confirm this reasoning. In pulling down the most ancient houses not an atom of dry-rot has been visible, but merely a decay in the timbers, occasioned by age, because the bricks inside and out were alike hard and sound; but where modern ones have been erected on the old sites, a very few years have been sufficient to prove that symptoms of dry-rot have manifested themselves in the basement, from the great degree of humidity which prevails there.

If such bricks, therefore, are not timely removed, all the art of man cannot prevent the effects of the dry-rot. It is the same with certain sorts of stone, which are always damp, be the weather what it may, and there the dry-rot makes the greatest havoc.

Bridge. It is needless to investigate ancient authors for a description of the primitive bridge, as its origin and elements are to be found in uncultivated nations of modern times. Stepping-stones, in shallow rivers, covered with planks from stone to stone, exhibit the incipient principles of piers and arches, which science has brought to their present perfection. In deeper rivers, an accumulation of stones forms a loftier pier; and, where the openings were sufficiently narrow, and the slabs of stone sufficiently long, or the art and strength of the untaught architect sufficient to the task, a roadway was formed from pier to pier, like the Vitruvian architrave of the primitive Tuscan temple. With the Greeks, who were a more maratime people, and more accustomed to navigation than the Romans, there is no doubt that ships and boats preceded, if they did not supersede, the use of bridges. In their brightest days, when their fine style of architecture was complete, when their porti-

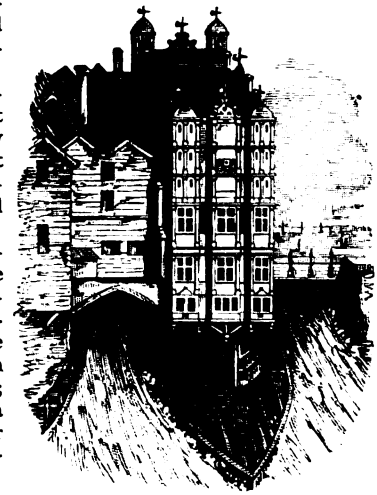
coes were crowded with paintings, and their streets with statues, the people of Athens waded or ferried over the Cephisus for want of a bridge. The Greeks do not seem to have valued the construction of the arch sufficiently to excel in bridge-building. No people of the ancient world carried the power of rearing the stupendous arch and the magnificent dome to such an extent as the Romans. After the construction of their great sewers, the aqueducts, and the cupola over the Pantheon of M. Agrippa, a bridge over the Tiber was of easy execution; and the invention of the architecture of stone bridges, as practised in its best and most effectual manner, must be conceded to this great and indefatigable people. The most celebrated bridges of ancient Rome were not distinguished by the extraordinary size of their arches, nor the peculiar lightness of their piers, but, like the rest of the magnificent works of this city, as far as construction is concerned, they are worthy of study from their excellence and durability. The span or chord of their arches seldom exceeded 70 or 80 feet, and the versed sine or height was nearly half of the chord, so that they were mostly semi-circular, or constituted a segment nearly of that form.

Among the most celebrated brigdes in modern times, or those built subsequently to the destruction of the Roman empire, are those of the Moors in Spain, who imitated and rivalled the best constructions of the Romans. The bridge of Cordova, over the Guadalquivir, is an eminent example of their success. The bridge over the Rhone, at Avignon, is one of the most ancient bridges of modern Europe. It was built by a religious society called the *Brethren of the Bridge*, which was established upon the decline of the second, and the commencement of the third race of French kings, when a state of anarchy existed, and there was little security for travellers, particularly in passing rivers, on which they were subject to the rapacity of banditti. The object of this society was to put a stop to these outrages, by forming fraternities for the purpose of building bridges and establishing ferries and caravansaries on their banks. The bridge of Avignon was commenced in 1176, and completed in 1178. It was composed of 18 arches. The length of the chord of the largest was 110 feet 9 inches, and its height 45 feet 10 inches. France can boast of many fine bridges, built during the last two centuries.

In Great Britain, the art of building bridges appears to have been diligently studied from early times. The most ancient bridge in England is the Gothic triangular bridge at Croyland in Lincolnshire, said to have been built in 860. The ascent is so steep that none but foot-passengers can go over it. The old bridge which connected London and Southwark was a very singular edifice, and a view of its peculiar architecture will serve to give our readers a notion of the state of knowledge in this important branch of hydraulic engineering at an early period.

This bridge appears to have been completed in the twelfth century, and a slight view of its narrow arches and massive abutments will serve to show how little science was displayed in its erection.

The bridge was crowded with buildings, and we select one of the most remarkable, called Nonesuch-House. Our view is taken from the *Chronicles of London Bridge*, one of the most elegant specimens of antiquarian learning in our language. Like most of the other buildings, this celebrated edifice also overhung the east and west sides of the bridge; and there presented to the Thames two fronts, of scarcely less magnificence than it exhibited to Southwark and the city; the columns, windows, and carving, being similarly splendid; and thus equally curious and interesting was the Nonesuch-House on London Bridge, seen from the water. Its southern front only, however, stood perfectly unconnected with other erections, that being entirely free for about fifty feet before it, and presenting the appearance of a large building projecting beyond the bridge on either side; having a square tower at each extremity, crowned by



short domes, or Kremlin spires, whilst an antiquely-carved gable arose in each centre. The whole of the front, too, was ornamented with a profusion of transom casement windows, with carved wooden galleries before them; and richly sculptured wooden panels and gilded columns were to be found in every part of it. In the centre was an arch of the width of the drawbridge, leading over the bridge; and above it, on the south side, were carved the arms of St. George, of the city of London, and those of Elizabeth, France and England quarterly, supported by the lion and dragon; from which circumstance only can we estimate the time when the Nonesuch-House was erected.

The new bridge is extremely striking from its contrast with the Gothic edifice, whose place it supplied. It consists but of five elliptical arches, which embrace the whole span of the river, with the exception of a double pier on either side, and between each arch a single pier of corresponding design: the whole is more remarkable for its simplicity than its magnificence. The following is a statement of the dimensions of the new bridge:—

Centre arch—span, 150 feet; rise, 32 feet; piers, 24 feet.

Arches next the centre arch—span, 140 feet; rise, 30 feet; piers, 22 feet.

Abutment arches—span, 130 feet; rise, 25 feet; abutment, 74 feet.

Total width, from waterside to waterside, 690 feet.

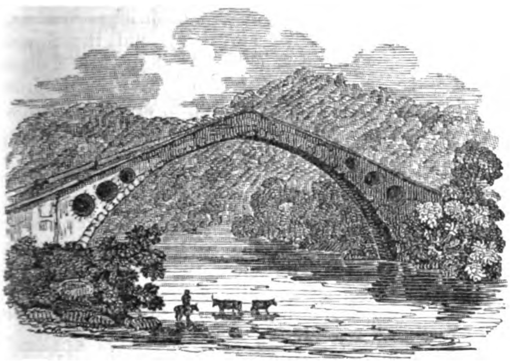
Length of the bridge, including the abutments, 930 feet; without the abutments, 782 feet.

Width of the bridge, from outside to outside of the parapets, 55 feet; carriage-way, 33 feet 4 inches.

Blackfriars bridge is handsome in design, and its elliptical arches are well suited to its situation, but its material is bad and perishable. This bridge was designed and erected by Robert Milne, an able Scotch architect. It was commenced in 1760, and com-

pleted in 1771. It is 995 feet long, and 43 feet 6 inches broad between the parapets. The centre arch is 100 feet in span, and 41 feet 6 inches in height. *Waterloo bridge* is one of the greatest architectural works of our times. It is the only bridge over the Thames which has a flat surface in its whole course. Its length is 1250 feet. It consists of 9 elliptical arches, each of 120 feet span, and 32 feet in height, Westminster bridge was commenced in 1740, and completed in 1750. It is 1220 feet long, and 44 feet between the parapets, has 13 large and 2 small arches, all semi-circular. The middle arch is 76 feet in span.

One of the most curious provincial bridges in Great Britain is that at Taff, in Glamorganshire. It is of one arch, and its space is rather more than 140 feet.



The architect of this bridge was a poor, uneducated man, and the persevering courage with which he pursued his object till the completion of the edifice, is worthy of record. His first attempts failed in consequence of the enormous pressure of the haunches or sides of the bridge, which forced up the key-stone, and to obviate this, he pierced the stone-work with cylindrical apertures, which remedied the defect. Prior to the erection of this bridge, that of the Rialto had the largest span of any in existence.

Metal bridges are the invention of British artists. The true elements of their construction are as yet but imperfectly understood. The first bridge of cast-iron ever erected is that over the Severn, about two miles below Colebrook-dale, in Shropshire. It is an arch composed of five ribs, forming the segment of a circle. Its chord is 100 feet long, and its height 45 feet. It was erected in 1777. The second cast-iron bridge was designed by Thomos Paine, the celebrated political writer, and was intended to have been taken to America; but, the speculator failing in his payments, the materials were afterwards used in constructing the beautiful bridge over the river Wear, at Bishop's Wearmouth, in the county of Durham. The chord of the arch is 240 feet long; the height, 30 feet. The Southwark bridge over the Thames is, at present, the finest iron bridge in the world. It consists of three arches. The chord of the middle arch is 240 feet long, and its height 24 feet. There are several other fine bridges of this kind in England. Mr. Telford proposed an iron arch of much larger dimensions than any now existing, to take the place of London bridge. The length of the chord was to be 600 feet, and its height 65. The plan was not however considered practicable.

Timber is the most ready, and perhaps the most ancient material used for the construction of bridges. The earliest timber bridge on record is that thrown by Julius Cæsar over the Rhine, and described in his *Commentaries*. Germany is the school for *wooden bridges*, as England is for those of iron. The most celebrated wooden bridge was that over the Rhine at Schaffhausen. This was 364 feet in length, and 18 feet broad. The plan of the architect was, that the bridge should consist of a single arch. The magistrates of the place, however, required that he should make it of two, and use the middle pier of a stone bridge, which had previously stood there. He did so, but contrived to leave it doubtful whether the bridge was at all supported by the middle pier. It was destroyed by the French, in April, 1799. The same architect and his brother have also erected several other fine arched wooden bridges. Several others have been erected in Germany, by Wiebeking, perhaps the most ingenious carpenter of our times.—In the United States, the Trenton bridge over the Delaware, erected by Burr in 1804, is the segment of a circle 345 feet in diameter. Its chord measures 200 feet; its height, or versed sine, is 32 feet, and the height of the timber framing of the arch, at its vertex, is no more than 2 feet 8 inches. The timber bridge over the Schuylkill, at Philadelphia, is of the extraordinary span of 340 feet. The versed sine is only 20 feet, and the height of the wooden framing at the vertex, 7 feet. Its architect was Wernwag, who built it in 1813. The bridge built by Palmer, over the Piscataqua, near Portsmouth, New Hampshire, in 1794, is the segment of a circle 600 feet in diameter. Its chord line measures 250 feet, its versed sine 27 feet 4 inches, and the height of the timber frame-work of the arch 18 feet 3 inches. It is put together with wooden keys. The same ingenious mechanic erected two other wooden bridges, one over the Merrimack, at Deer Island, near Newburyport, of 160 feet diameter, finished in 1792, and the other over the Schuylkill at Philadelphia, of 194 feet chord, and 12 feet versed sine, being the segment of a circle 796 feet in diameter. This was finished in 1803.

There were suspension bridges both in America and India long prior to their general use in this country.

The little river of Chambow, which flows from the lake of Coley, separates the beautiful village of Guanando from that of Penipe. It runs through a ravine, the bottom of which is elevated 2400 metres above the level of the sea; and which has long been famous for the production of cochineal, in the preparation of which, the inhabitants have been employed from the remotest antiquity. The river (says M. de Humboldt) is crossed by one of those bridges of cords which the Spaniards call *puente de maroma*, and the Peruvian Indians, *cimppacha*, from *cimppa*, ropes, and *chaca*, a bridge. The ropes, which are three or four inches in diameter, are made from the fibrous roots of the American agavey. They are attached to a wooden scaffolding composed of the trunks of several trees, erected on the shore, on each side of the river, and upon them are laid small round pieces of bamboo, placed transversely.

As the weight of the bridge causes the trees to bend towards the middle of the river, and as it would be imprudent to strain them with too much force, it becomes necessary (although the shores of the river are not very high) to construct steps or ladders at the two extremities of the bridge. This bridge is

120 feet long, and 7 or 8 feet wide; but there are others of this construction, whose dimensions are considerably larger.

These structures, which the South Americans made use of long prior to the arrival of the Europeans, greatly resemble the bridges of chains that are met with in China, and in the interior of Africa. Mr. Turner, in his interesting *Voyage to Thibet*, has given the plan of the bridge of Ichinchieu, near the fort of Chuka (lat. 27° 14′), which is 140 feet long, and which may be passed over on horseback. This bridge is supported by five chains covered with pieces of bamboo.

All travellers have spoken of the great danger which attends the passage of these rope bridges, which are suspended like ribands across a deep ravine or impetuous torrent. The danger, however, is not very great (says Baron Humboldt), when a single person passes over by himself, especially if he run as quickly as possible, throwing the body forward. But the oscillations of the ropes become very violent when the traveller is conducted by an Indian, who walks much quicker than he, or if affrighted by the appearance of the water, seen between the interstices of the bamboos, he is imprudent enough to stop in the middle, and lay hold of the ropes which serve for balustrades.

A rope bridge seldom remains in good condition longer than twenty or twenty-five years; and even then it becomes necessary to replace some of the ropes every eight or ten years. But the internal regulations of this country are so lax, that it is not uncommon to see bridges, in which the flooring of bamboo is broken into large piece; and it is then necessary to walk with much circumspection over those ancient structures, in order to avoid the holes, which are sometimes large enough to precipitate the unwary traveller into the water, or the ravine beneath. A few years before my arrival at Penipe (says M. Humboldt), in consequence of long continued rains, which were succeeded by a very dry wind, the suspension bridge of the Rio Chambo fell to pieces. Four Indians were drowned in the river, which is very deep, and its current extraordinarily rapid.

The ancient Peruvians constructed bridges of wood, which rested upon piles of stone; but they most commonly contented themselves with bridges of ropes, which are extremely useful in a mountainous country, where the depth of the ravines, on the impetuosity of the torrents, prevent the constructing of piles. The violence of their swinging may be diminished by lateral ropes attached to the middle of the bridge, and stretching diagonally towards the shore.

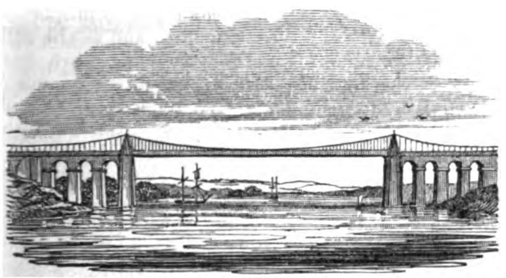
It is by means of a bridge of ropes of extraordinary length, which may be traversed by loaded mules, that the South Americans have succeeded (within these few years) in establishing a permanent communication between the towns of Quito and Lima, after having uselessly expended a million of francs in constructing near Santa, a stone bridge over a torrent which descends from the Cordilleras of the Andes.

The simplicity of construction observable in these fragile works of art, and the small expenditure of time and labour which they require, were advantages particularly suited to the narrow genius and slender mechanical knowledge of this simple people. No doubt, if these bridges were exposed for a short time to the vicissitudes of an European, or at least of an English climate, catastrophes similar to that recorded by Baron Humboldt, would occur so frequently, as to oblige the South Americans to construct their bridges of more durable and solid materials. And as we find that the progress of mankind, in the path of science, has been rapid in proportion to the necessities of their situation, and as the calls upon their energies and understanding have been more or less imperative, so, no doubt, the science of bridge-building with the South Americans, will ultimately approach to the perfection of the European art.

The suspension principle for bridges has likewise been adopted in India. In the Calcutta government gazette, is a description of a suspension-bridge, which has lately been erected at Aligpore, of materials quite novel in the history of bridge-building, and in a manner alike surprising and ingenious. This bridge, which was constructed by Mr. Cohen Shakespeare, consists entirely of cane with iron fastenings, and is 130 feet in length, and 5 in width. The canes, which are from 100 to 225 feet in length, and from 1 to nearly 2 inches in diameter, were procured from the north-eastern frontier (where they may be had for the trouble of collecting them), and sent to Calcutta coiled up like ropes. Eighteen canes form the bearings; these are lashed together at each end of the bridge, and upon them are laid cross slips of bamboo, as in the construction of rope bridges. Not only the roadway, but also all the contrivances for steadying the bridge, and preventing oscillation, are of iron, and are well arranged. These materials, of course, prevent the danger and difficulty which would attend the passage; the bridges described by M. Humboldt in these parts were entirely of cane. The appearance of the arch is described as singularly light, even more so than rope; and it is in reality lighter as a whole, because the cross bamboo slips, forming the roadway, are lashed at once to the canes; and thus it becomes firmer than in the rope bridge, in which the treadway is distinct, and lies over the strands. The strength and durability of the cane are by some considered equal to that of rope; this is a question that time will solve. Should the cane, however, last only a season or two of the rains, and it is strongest when kept moist, the advantages gained to the country will be incalculable, as it abounds with that cheap and useful commodity.

Suspension bridges were in use in Europe in the time of Scamozzi, as may be seen in his *Del Idea Archi*, 1615; yet the principles requisite to determine the structure of this kind of bridges had not been made public before the time of Bernouilli. The use of these bridges is of great antiquity in mountainous countries. The most remarkable bridge of suspension in existence is that lately constructed by Mr. Telford over the Menai strait, between the isle of Anglesea and Caernarvonshire in Wales. It was finished in 1825. The roadway is 100 feet above the surface of the water at high tide. The opening between the points of suspension is 560 feet. The platform is about 30 feet in breadth. The whole is suspended from 4 lines of strong iron cables by perpendicular iron rods, 5 feet apart. The cables pass over rollers on the tops of pillars, and are fixed to iron frames under ground, which are kept down by masonry. The weight of the whole bridge, between the points of suspension, is 489 tons. Some notion

of the vast space and gigantic proportions of this bridge may be collected from the fact exhibited in the accompanying engraving, of a large two-masted vessel being able to sail at once beneath its aerial roadway.



There is but one circumstance which appears at all to affect the stability of its equilibrium, and that is the heavy and measured tread of a long line of military. The whole weight of a number of men, whose feet drop at the same instant of time, would affect any suspension bridge.

The following remarks on the *construction* of bridges are from Bigelow's *Technology:* "The construction of small bridges is a simple process, while that of large ones is, under certain circumstances, extremely difficult, owing to the fact, that the strength of materials does not increase in proportion to their weight, and that there are limits, beyond which no structure of the kind could be carried, and withstand its own gravity. Bridges differ in their construction, and in the materials of which they are composed. The principal varieties are the following:—

"*Wooden bridges.* These, when built over shallow and sluggish streams, are usually supported upon piles driven into the mud at short distances, or upon frames of timber. But, in deep and powerful currents, it is necessary to support them on strong stone piers and abutments, built at as great a distance as practicable from each other. The bridge between these piers consists of a stiff frame of carpentry, so constructed with reference to its material, that it may act as one piece, and may not bend or break with its own weight, and any additional load to which it may be exposed. When this frame is straight, the upper part is compressed by the weight of the whole, while the lower part is extended, like the tie-beam of a roof. But the strongest wooden bridges are made with curved ribs, which rise above the abutments in the manner of an arch, and are not subjected to a longitudinal strain by extension. These ribs are commonly connected and strengthened with diagonal braces, keys, bolts, and straps of iron.

"*Stone bridges.* These, for the most part, consist of regular arches, built upon stone piers constructed in the water, or upon abutments at the banks. Above the arches is made a level or sloping road. From the nature of the material, these are the most durable kind of bridges, and many are now standing which were built by the ancient Romans. The stone piers, on which bridges are supported, require to be of great solidity, especially when exposed to rapid currents, or floating ice. Piers are usually built with their greatest length in the direction of the stream, and with their extremities pointed or curved, so as to divide the water, and allow it to glide easily past them. In building piers, it is often necessary to exclude the water by means of a *coffer-dam.* This is a temporary enclosure, formed by a double wall of piles and planks, having their interval filled with clay. The interior space is made dry by pumping, and kept so till the structure is finished.

"*Cast-iron bridges.* These have been constructed, in England, out of blocks or frames of cast-iron, so shaped as to fit into each other, and, collectively, to form ribs and arches. These bridges possess great strength, but are liable to be disturbed by the expansion and contraction of the metal with heat and cold.

"*Suspension bridges.* In these the flooring or main body of the bridge is supported on strong iron chains or rods, hanging in the form of an inverted arch, from one point of support to another. The points of support are the tops of strong pillars or small towers, erected for the purpose. Over these pillars the chain passes, and is attached at each extremity of the bridge to rocks, or massive frames of iron, firmly secured under ground. The great advantage of suspension bridges consists in their stability of equilibrium, in consequence of which a smaller amount of materials is necessary for their construction than for that of any other bridge. If a suspension bridge be shaken, or thrown out of equilibrium, it returns by its weight to its proper place, whereas the reverse happens in bridges which are built above the level of their supporters.

"*Floating bridges.* Upon deep and sluggish water, stationary rafts of timber are sometimes employed, extending from one shore to another, and covered with planks, so as to form a passable bridge. In military operations, temporary bridges are often formed by planks laid upon boats, pontons, and other buoyant supporters." See Centering.

Brig, or Brigantine; a square-rigged vessel, with two masts. The term is applied to different kinds of vessels, by mariners of different countries. The term *brigantine* is also applied to a light, flat, open vessel, with 10 or 15 oars on a side, furnished also with sails, and able to carry upwards of 100 men. The rowers, being also soldiers, have their muskets lying ready under the benches. Brigantines are frequently made use of, especially in the Mediterranean, for the purpose of piracy, from which they derive their name. They are very fast sailers.

Brigade; in general, an indeterminate number oi regiments or squadrons. In the English army, a brigade of infantry is generally composed of 3 regiments: a brigade of horse, of from 8 to 12 squadrons; and one of artillery, of 5 guns and a howitzer. In the United States' army, the brigade is commonly composed of two, but sometimes more regiments. A number of brigades form a division, and several divisions an army-corps. A brigade-major is the chief of the brigade staff. A brigadier-general is the officer who commands a brigade. In the British service, this rank is now abolished. In the United States' service, he is next in rank to the major-general, who is the highest officer under the president, as commander-in-chief. *Brigadier-general* is also the title of the chief of the staff of an army-corps. In the French military language, *brigade*, in the cavalry, signifies a corporal's guard. Hence *brigadier* signifies a corporal.

Brigandine; a kind of defensive armour, consisting of thin jointed scales of plate, pliant and easy to the body.

Brimstone. Sulphur as first obtained, is mixed with foreign bodies, and, for the purpose of purification, is melted in a close vessel, by which the impurities are allowed to subside. It is then poured, in the liquid state into cylindrical moulds, in which it becomes hard, and is known in commerce by the name of *roll brimstone*. The inspired historian (Gen. xix. 24) relates that Sodom and Gomorrah were destroyed by fire from heaven. Showers of fire have been observed by Bergmann (occasioned by electricity), and showers of brimstone may be produced from the sulphuric acid which exists in the atmosphere.

Brittleness, in *Natural Philosophy*; that quality of bodies by which they are soon and easily broken by pressure or percussion.

Broach; any thing which will pierce through; a pin; that part of certain ornaments by which they are stuck on; the ornament itself. Among the Highlanders of Scotland, there are preserved, in several families, ancient broaches of rich workmanship, and highly ornamented. Some of them are inscribed with characters to which particular virtues were attributed, and seem to have been used as a sort of amulet or talisman.

Broad Piece; a denomination that has been given to some English gold pieces broader than a guinea, particularly Caroluses and Jacobuses.

Broadside, in a naval engagement; the whole discharge of the artillery on one side of a ship of war, above and below. A squall of wind is said to throw a ship on her broadside, when it presses her down in the water, so as nearly to overset her.

Broad-Sword; a sword with a broad blade, designed chiefly for cutting, used by some regiments of cavalry and Highland infantry in the British service. It has, in general, given place to the sabre among the cavalry. The claymore or broad-sword was formerly the national weapon of the Highlanders.

Brocade; a stuff of gold, silver, or silk, raised and enriched with flowers, foliage and other ornaments. Formerly, it signified only a stuff wove all of gold or silver, or in which silk was mixed; at present, all stuffs, grograms, satins, taffetas and lustrings are so called, if they are worked with flowers or other figures.

Brome; a peculiar substance discovered in 1826. It is obtained from the bittern of sea-water, or the washings of the ashes of sea-weed. It is a dark-red liquid, of a specific gravity of 2.965, highly volatile, and emits copious red fumes at the ordinary temperature of the air. It boils at 116°. The vapour does not sustain the combustion of a candle, though several of the metals burn in it. It possesses the bleaching powers of chlorine, and, like that substance, is eminently hostile to life; a single drop of it placed upon the bill of a bird being sufficient to kill it. With oxygen and hydrogen it forms acids. Its properties have led to the opinion, that it might be a compound of chlorine and iodine; but as neither of these substances have been detected in it, we are, for the present at least, obliged to regard it as a simple element.

Bronchant, in *Heraldry*; a term used by the French heralds to denote the situation of any beast, when placed on a field strewed with fleurs-de-lis.

Bronchia, in *Anatomy*; the two primary divisions of the trachea or windpipe, which convey the air to the lungs.

Bronchial Arteries arise from the descending aorta, and accompany the bronchiæ into the lungs.

Bronchial Glands; absorbent glands situated at the root of the lungs.

Bronchial Veins are those which accompany the bronchial arteries.

Bronchotomy, in *Surgery*; the operation of cutting into the trachea or windpipe.

Bronchus, in *Anatomy*, properly denotes the lower part of the aspera arteria, dividing into bronchiæ, or branches.

Bronzes; works of art cast in bronze. The ancients used bronze for a great variety of purposes; arms and other instruments, medals and statues, of this metal, are to be found in all cabinets of antiquities. Egyptian idols of bronze are contained in the British Museum. The most celebrated antique bronze statues are, the sleeping satyr; the two youthful athletes; the colossal equestrian statue of Marcus Aurelius, at Rome; the Hercules of the capitol; the colossal head of Commodus; the statue of Septimius Severus in the Barberini palace. The horses of St. Mark, at Venice, are of pure copper. On tables of bronze were inscribed laws, edicts, and treaties. 3000 of these were destroyed by fire in the time of Vespasian. Bass-reliefs, vaults, and doors of public edifices, were ornamented with decorations of the same metal. Urban VIII. took from the Pantheon alone 450,000 pounds of bronze, which he used for the ornaments of St. Peter's, and for the cannon of the castle of St. Angelo. One of these was composed wholly of bronze nails, taken from the portico, and bore the inscription, *Ex clavis trabalibus porticûs Agrippæ*. The ancients considered this metal as naturally pure; all their instruments of sacrifice, and sacred vessels, were therefore of bronze. They also believed it endowed with the power of driving away spectres and malignant spirits. The words *moneta sacra* are found only on bronze medals. It was sacred to the gods; and the Roman emperors, who struck gold aud silver coins, could not strike them of bronze without the permission of the senate; hence the inscription S. C. (*Senatus consulto.*) The moderns have also made much use of bronze, particularly for statues exposed to accidents, or the influence of the atmosphere, and for casts of celebrated antiques. The moulds are made on the pattern, of plaster and brick-dust. The parts are then covered on the inside with a coating of clay as thick as the bronze is intended to be. The mould is now closed, and filled on its inside with a nucleus or core of plaster and brick-dust, mixed with water. When this is done, the mould is opened, and the clay carefully removed. The mould, with its core, are then thoroughly dried, and the core secured in its position by bars of bronze, which pass into it through the external part of the mould. The whole is then bound with iron hoops, and the melted bronze is poured in through an aperture left for that purpose: of course, the bronze fills the same cavity which was occupied by the clay, and forms a metallic covering to the core. It is afterwards made smooth by mechanical means.

Bronzing. Bronze of a good quality acquires, by oxidation, a fine green tint, called *patina antiqua*, or, by the Romans, *ærugo*. Corinthian brass receives in this way a beautiful green colour. This appearance is imitated by an artificial process, called *bronzing*. A solution of sal ammoniac and salt of sorrel

in vinegar is used for bronzing metals. Any number of layers may be applied, and the shade becomes deeper in proportion to the number applied. For bronzing sculptures of wood, plaster, figures, &c., a composition of yellow ochre, Prussian blue, and lampblack, dissolved in glue-water, is employed.

Brown; a dusky kind of pigment, inclining somewhat to redness.

Bruiser, in *Mechanics;* the name of a concave tool used for grinding and polishing the specula of telescopes. It is made of brass, about a quarter of an inch thick, and hammered as near to the gauge as possible. It is tinned on the convex side, and made equally broad at bottom and top. This serves to reduce the figure of the grinding stones, when they are too convex, and to rub down any gritty matter that happens to be mixed with the putty, before the speculum is applied to the polisher.

Bruising, in *Pharmacy;* the operation of breaking or pounding a thing coarsely, or by halves; frequently practised on roots, woods, and other hard bodies, to make them yield their juice more freely than they would do in their natural state.

Buccinator Musculus, in *Anatomy,* arises from the alveolus, containing the last grinder of the lower jaw; from the coronoid process, and from the tubercle behind the socket of the last grinder of the upper jaw; its fibres proceed over the membrane of the mouth, where it lines the cheek, and terminates in both the lips and in the angle of the mouth. It draws the lips backwards towards its posterior attachments, and when the lips are made fixed parts by the action of the obicularis oris, it will thrust any matter intervening between the cheek and the cavity of the mouth, into that cavity, for the purposes of mastication and deglutition.

Buccula, in *Anatomy;* the fleshy part under the chin.

Bucking. See Bleaching.

Buffet; anciently, a little apartment, separated from the rest of the room, for the disposing of china, glass, &c. It is now a piece of furniture in the dining-room, called also a *side-board,* for the reception of the plate, glass, &c. In France, the principal houses have a detached room, called *buffet,* decorated with pitchers, vases, fountains, &c.

Buffone (*Italian*); buffoon; a comic singer in the *opera buffa,* or the Italian *intermezzo.* The Italians, however, distinguished the *buffo cantante,* which requires good singing, from the *buffo comico,* in which there is more acting. *Buffoonery* is the name given to the jokes which the buffoon introduces. The word is, no doubt, borrowed from the Low Latin, in which the name *buffo* (cheeked), was given to those who appeared on the theatre with their cheeks puffed up, to receive blows on them, and to excite the laughter of the spectators. Hence *buffa,* cheeks; *buffare,* to puff up the cheeks. Afterwards, the name came to signify a *mimic,* a *jester* in general.

Bugle-Horn. See Horn.

Building Materials. Our article on Bricks contains a general view of the best modes of preparing argillaceous earths for the purposes of building. There are however other materials, which must be noticed here. We may commence with stone, which is a dense, coherent body of considerable hardness and durability, but generally brittle. It possesses these qualities, in various degrees, according to the nature of its chemical elements, or the state of aggregation of its parts.

The structure of stone is either laminated, or granulated, or of a mixed kind.

The chemical constituents of building stones, are silica, alumina, lime, magnesia, and metals, combined with acids, water, and sometimes with alkalies: some other chemical elements are found in building stones, but not often in sufficient quantity to affect the nature of the stones.

Laminated stones consist of thin plates, or layers, cohering more or less strongly together; when the layers are of considerable size, and cohere so slightly that they may be easily separated, the stones are said to be slaty. The layers are always nearly parallel to the quarry-beds of the stones, and they should always be horizontal, or as nearly so as possible in a building; otherwise the action of the weather will cause them to separate, and fall off in flakes. In sand stones, the direction of the layers may often be discovered by their different shades of colour; in others by the positions of minute scales of mica, which always lie parallel to the layers. In most stones the direction of the layers may be ascertained by the facility with which the stone yields to the tool in that direction; but a considerable degree of practice is necessary to acquire so nice a discrimintion of resistance, and good workmen only attain it. Among laminated stones, those are the most durable in which the laminæ are least distinct, and the texture uniform. When the laminæ do not perfectly cohere, they are soon injured by frost, and they are wholly unfit for places alternately wet and dry,

Granular stones consist of distinct concretions resembling grains, either of the same, or of different simple minerals cohering together. When the structure is uniform, and the grains or concretions are small, stones of this kind are always strong and durable, if the concretions themselves be so. Granular stones are sometimes open and porous, but when they are uniformly so, they seldom suffer materially by frost; because their uniform porosity allows the expansive force of congealing water to be distributed in every direction.

Stones of a compound structure, partly laminated and partly granular, have more or less of the characters of the two classes before described; for it may be observed in coarse-grained granite that the laminated structure of some of its parts renders it very susceptible of disintegration. All kinds of stone obtained from quarries are found divided by vertical or inclined seams, which are sometimes so close that they cannot be distinguished till the stones are wrought; but they often separate under the tool at such seams; and it is not safe to employ stone to resist any considerable transverse strain, on account of the difficulty of knowing where those seams are.

In the present state of our knowledge of this important subject, we may attribute the failure of building stones to two causes; the one chemical, and the other mechanical, which we shall here distinguish by the terms *decomposition* and *disintegration.*

Decomposition consists in the chemical elements of a stone entering into new combinations with water, oxygen, or carbonic acid gas. Stones containing such elements as are readily acted upon by these external causes will be found most subject to decompose; and the process will be, in many kinds, much hastened by a loose texture.

Stones containing saline matter, as the felspar of some granites, are acted upon by water; particularly where the soluble salt is in considerable proportion; and in some stones the application of salt water soon destroys them. Dolomieu says, the houses at Malta are built with a fine-grained limestone, of a loose and porous texture, which speedily moulders away when it has been wetted with sea-water.

Stones containing iron, which is not in a maximum state of oxidation, are often destroyed by the absorption of oxygen and carbonic acid; the presence of moisture accelerates their decomposition, and it is always still farther hastened by increasure of temperature. According to the observations of Kirwan, stones containing iron in a low state of oxidation are of a black, a brown, or a bluish colour; and in some instances, when united with alumina and magnesia, they are of a gray; the former, as they become more oxygenized, change to purple, red, orange, and finally pale yellow; the latter become at first blue, then purple, red, &c. (Kirwan's *Geological Essays*, p. 145, 6.) But stones containing iron, combined with its maximum of oxygen, do not readily decompose, such as red porphyry, jaspers, &c. When stones contain magnese, lime, alumina, carbon, or bitumen, in particular states, they are subject to decomposition, from the affinities of one or other of these bodies; but nothing very decisive is, or perhaps can be, known respecting such changes, till some improvement be made in analytical chemistry, by which the state of combination of the constituents of minerals can be determined with more certainty.

Disintegration is the separation of the parts of stones by mechanical action. The chief cause is the congelation of water in the minute pores and fissures of stones, which burst them open, or separate small parts according as the structure is slaty or irregularly granulated. The south sides of buildings, in northern climates, are most subject to fail; because the surface is often thawed and filled with wet in the sunny part of the day, and frozen again at night. This repeated operation of freezing is also very injurious to sea walls, the piers of bridges, and other works exposed alternately to water and frost. An illustration of this fact will be found in the bridges crossing the Thames at Westminster and Blackfriars, as the materials of which they are composed may readily be detached in the winter season by the slightest external force.

Proportional strength of various subtances in bearing pressure.—Fine freestone, 1; alder, ash, birch, white fir, willow, 6; lead $6\frac{1}{4}$; beech, cherry, hazel, $6\frac{3}{4}$; red fir, holly, elder, plane, apple, 7; walnut, thorn, $7\frac{1}{2}$; elm, ash, $8\frac{1}{2}$; box, yew, plumb-tree, oak, 11; bone, 22; brass, 50; iron 107. These results, however, differ materially from some others.

A yard of oak, an inch square, will bear in the middle, for a very short time, 330 pounds; but, according to Emerson, a third or fourth of this is as much as can be applied in practice. *Mech.* p. 114. It is in fact much more; for, in general, the weight supported ought not to produce a sensible bending; and this practical limit requires more attention than it has hitherto received. Allowance must also be made for the occasional depredations of insects.

Wood is from 7 to 20 times weaker transversely than longitudinally. It becomes stronger both ways when dry.

A cylinder, an inch in diameter, will bear, when loaded to $\frac{1}{4}$ of its whole strength, if of fir, 8.8 cwt.; if of rope, 22 cwt.; if of iron, 6.75 tons, or 135 cwt.

Count Rumford found the cohesive strength of a cylinder of iron, an inch in diameter, 63,466 or 63,173 pounds, the mean 63,320. *Phil. Trans.* 1797. This is only 1-20th more than Emerson.

In Buffon's experiments, b, d, and l being the breadth, depth, and length of a beam of oak in inches, the weight which broke it, in pounds, was $b\,d^2 \left(\frac{54.25}{l} - 10\right)$.—*Robison.*

A piece of sound oak, an inch square, bears 8000 pounds directly, and is broken transversely by 200, at the distance of 12 inches from the fulcrum. Iron is not cheaper than wood of equal strength. The immediate transverse strength of lateral adhesion of most substances exceeds their direct cohesive strength, but the difference is less in fibrous substances than in others.—*Robison.* Coulomb found them nearly equal.

Six of the pieces of oak employed in Girard's experiments broke under the pressure of 2710 pounds on a square inch at a mean, but fifteen others supported a much greater load.

A rib of cast iron, with abutments of $29\frac{1}{2}$ feet span, 11 inches high in the centre, supported 11,130 pounds, but sunk $3\frac{5}{8}$ inches, and rose again three-quarters of an inch; without abutments it broke with 6174 pounds. Bars of iron, one inch square and three feet long, weighing nine pounds, sunk about an inch, and broke with 960 pounds.

If a piece be spliced on a divided beam, equal in depth to half the depth of the beam, the strength is greater than that of the entire beam, in the ratio of 1 to 0.54, very nearly.

Coulomb found the lateral cohesion of brick and stone only $\frac{1}{11}$ more than the direct cohesion, which, for stone, was 215 pounds for a square inch; for good brick, from 280 to 300. Supposing this lateral cohesion constant, a pillar will support twice as much as it will suspend, and its angle of rupture will be 45 degrees. From the same supposition it may inferred, that the strongest form of a body of given thickness for supporting a weight, is that of a circle, since the power of the weight in the direction of every section varies as the length of that section, and the strength is therefore equal throughout the substance. But if the cohesion be increased, like friction, by pressure, and supposing, with Amontons, that this increase, for brick, is three-fourths of the weight, the plane of rupture of a prismatic pillar will form, according to Coulomb, an angle of 63° 26′ with the horizon, and the strength will be doubled. On both suppositions the strength is simply as the section. It is of the less consequence to investigate the lateral pressure of soft materials, as they are generally liable to be penetrated by water, which acts according to the laws of hydrostatics.

Supposing the pressure of the materials to be vertical only, a quadrant of a circle will support a horizontal road in equilibrio, if the depth of the bridge in the middle be to the radius as 1 to $6\frac{1}{4}$, that is, about one-ninth of the span. *Emers. Mech.* But this appears to be only an approximation.

A catenaria will support a horizontal road 100 feet above it, if the height and half the span be each 150. A logarithmic curve will form a half arch of equilibrium, if the road be horizontal. *Emerson.* But all these proportions would make the bridge too heavy.

Perronet thinks that a bridge of 500 feet span might stand; the bridge of Nantes having sunk to a radius of 500 feet.

In the construction of bridges, Professor Robison observes, that something is to be allowed for the lateral pressure of the materials; and that the cohesive strength of the arch, and its resistance to any force in the manner of a lever, ought to be taken into the calculation. These remarks are extremely just, but they do not appear to have been practically considered, except so far as theory has been modified by experience.

If there be an arch composed of stones of a given magnitude considered as perfectly solid, the effect of a weight bearing on the key-stone will be a displacement of the pressure on the abutment; the centre of pressure on the abutment will be removed to a distance, which is to the height of the arch nearly as the tangent of the immediate change of the direction of the new compound thrust of the key-stone to the radius. It seems to be desirable that this displacement should never exceed the limits of the abutments themselves.

Supposing the pressure of the materials vertical only, the curve may be constructed mechanically, without difficulty, by making the centre of each portion of it at a distance below the arc which is inversely as the distance of the arc from the road. In the case of a horizontal road, the greatest curvature will be where this distance is a mean proportional between the radius of curvature at the vertex and the depth of the materials at the same point. The following is a table of the cohesive force of building materials:

Names of Substances.	Cohesive force of a square inch in lbs. Avoirdupois.
Brick	0.300
Marble, white	9.000
Mortar, 16 years old	0.050
Plaster of Paris	0.072
Slate, Welsh	12.800
Stone, Givry, hard	2.166
———, soft	0.385
——, Portland	0.784
——, homogeneous, white, of a fine grain	0.207

BULIMIA. The persons attacked by this disorder are tormented with an insatiable hunger. When their stomach is surfeited, they are seen to faint, and throw off the food which they have taken, half digested, and with violent pain. It usually appears as a concomitant of other diseases. It occurs during certain intermittent fevers, in certain diseases of the stomach and bowels, particularly in such as are produced by the tape-worm; and is also common after fevers, by which the strength of the patient is exhausted. In this last case, it arises from the effort of all parts of the body to supply the lost flesh and strength. In certain cases, however, the extraordinary desire for food seems to be caused by a particular condition of the stomach, which digests with too great rapidity. This is observed sometimes in women during their pregnancy, in young people who exercise too violently, and in persons who take much high-seasoned and heating food. In this case, the desire is not to be considered as a disease, but only as an excessive appetite. As a disease, its consequences are dreadful—leanness, pulmonary fevers, consumption, constipation, dropsy.

BULK-HEADS; certain partitions or walls built up in several places of a ship between two decks, either lengthwise or across, to form and separate the various apartments.

BULL, in *Astronomy;* the constellation Taurus.

BULLET, an iron or leaden ball, or shot, wherewith fire-arms are loaded.

BULLION is uncoined gold or silver, in bars, plate, or other masses. The word *bullion* was of frequent use in the proceedings respecting the Bank of England (see BANK), from 1797, when the order of council was issued, that the Bank should discontinue the redemption of its notes by the payment of specie, to 1823, when specie payments were resumed; for, by a previous law, the Bank was authorized to pay its notes in uncoined silver or gold, according to its weight and fineness. The investigations of the bullion committees, and the various speculations on the subject of bullion, related to the supply of gold and silver, whether coined or not, as the basis of the circulating medium.

BULWARK. See BASTION.

BUM-BOAT; a small boat used to sell vegetables, &c., to ships lying at a distance from shore.

BUNGALOW; an East Indian term for a house with a thatched roof.

BUNT; the middle part or cavity of the principal square-sails, as the main-sail, fore-sail, &c. If one of them be supposed to be divided into four equal parts, from one side to the other, the two middle divisions, which comprehend half of the sail, form the limits of the bunt.

BUNTING; a thin woollen stuff, of which the colours and signals of a ship are usually formed.

BUOY; any floating body employed to point out the particular situation of any thing under water, as of a ship's anchor, a shoal, &c.—The *can* buoy is of a conical form, and painted with some conspicuous colour; it is used for pointing out shoals, sand-banks, &c.—The *cask* buoy is in the form of a cask; the larger are employed for mooring, and are called *mooring* buoys; the smaller for cables, and are known as *cable* buoys. The buoy-rope fastens the buoy to the anchor, and should be about as long as the depth of the water where the anchor lies; it should also be strong enough to draw up the anchor in case the cable should break.

BUOY, LIFE. The *life* or *safety* buoy is intended to keep a person afloat till he can be taken from the water. It should be suspended from the stern of the ship, and let go as soon as any person falls overboard. A light may be attached to it, both to indicate its position to the individual in danger, and to direct the course of the boat sent to relieve him, if the accident happens by night. Captain Basil Hall thus describes the apparatus employed in the British service:—"The life-buoy, now commonly used in the navy, is the invention of Lieutenant Coots, of the Royal Navy. It consists of two hollow copper vessels connected together, each about as large as an ordinary sized pillow, and of buoyancy and capacity sufficient to support one man standing upon them. Should there be more than one person requiring support, they can lay hold of rope beckets, fitted to the buoy,

and so sustain themselves. Between the two copper vessels there stands up a hollow pole, or mast, into which is inserted, from below, an iron rod, whose lower extremity is loaded with lead, in such a manner, that when the buoy is let go, the iron slips down to a certain extent, lengthens the lever and enables the lead at the end to act as ballast. By this means the mast is kept upright, and the buoy prevented from upsetting. The weight at the end of the rod is arranged so as to afford secure footing for two persons, should that number reach it; and there are also, as I said before, large rope beckets through which others can thrust their head and shoulders, till assistance is rendered.

"At the top of the mast is fixed a port-fire, calculated to burn about twenty minutes, or half an hour; this is ignited most ingeniously by the same process which lets the buoy fall into the water. So that a man falling overboard at night is directed to the buoy by the blaze on the top of its pole or mast, and the boat sent to rescue him also knows in what direction to pull. Even supposing, however, the man not to have gained the life-buoy, it is clear that, if above the surface at all, he must be somewhere in that neighbourhood; and if he shall have gone down, it is still some satisfaction, by recovering the buoy, to ascertain that the poor wretch is not left to perish by inches.

"The method by which this excellent invention is attached to the ship, and dropped into the water in a single instant, is perhaps not the least ingenious part of the contrivance. The buoy is generally fixed amid ships, over the stern, where it is held securely in its place by being strung, or threaded, as it were, on two strong perpendicular rods fixed to the taffrail, and inserted in holes piercing the frame-work of the buoy. The apparatus is kept in its place by what is called a slip-stopper, a sort of catch-bolt or detent, which can be unlocked at pleasure by merely pulling a trigger; upon withdrawing the stopper the whole machine slips along the rods, and falls at once into the ship's wake. The trigger, which unlocks the slip-stopper, is furnished with a lanyard, passing through a hole in the stern, and having at its inner end a large knob, marked 'Life-Buoy;' this alone is used in the day-time. Close at hand is another wooden knob, marked 'Lock,' fastened to the end of a line, fixed to the trigger of a gun-lock primed with powder, and so arranged that, when the line is pulled, the port-fire is instantly ignited, while, at the same moment, the life-buoy descends, and floats merrily away, blazing like a light-house.

"The gunner, who has charge of the life-buoy lock, sees it freshly and carefully primed every evening at quarters, of which he makes a report to the captain. In the morning the priming is taken out, and the lock uncocked. During the night a man is always stationed at this part of the ship, and every half-hour, when the bell strikes, he calls out 'Life-Buoy!' to show that he is awake and at his post."

Burbas, in *Commerce;* a small coin still circulated at Algiers, with the arms of the Dey struck on both sides, worth half an asper.

Burden, or Burthen; 1. the contents of a ship; the quantity or number of tons which a vessel will carry; 2. the part of a song which is repeated at every verse or stanza, is called the *burden of the song*, from the French *bourdon*, drone or base, because they are both characterized by an unchangeable tone, and bear upon the ear with a similar monotony.

Bureau; a writing-table; afterwards used to signify the chamber of an officer of government, and the body of subordinate officers who labour under the direction of a chief. *Bureau system*, or *bureaucracy*, is a term often applied to those governments in which the business of administration is carried on in departments, each under the controul of a chief; and is opposed to those in which the officers of government have a co-ordinate authority. Sometimes a mixture of the two systems is found. Thus the business of the executive branch of government may be carried on by bureaus, while the administration of justice is in the hands of co-ordinate judges. The *bureau des longitudes*, in France, corresponding to the English *board of longitude*, is charged with the publication of astronomical and meteorological observations, the correction of the astronomical tables, and the publication of the *Connaissance des Temps*, an astronomical and nautical almanac. (See Almanac in our *Second Division*.) According to the parliamentary usage of France, at the opening of each session, the chamber of deputies is divided into nine *bureaus*, composed of an equal number of deputies, designated by lot. Each bureau appoints its own president, and discusses all matters referred to it by the chamber separately. A reporter is appointed by each bureau, and, after the discussion by bureaus, the nine reporters meet, discuss the subject, and appoint one of their number to report to the whole chamber, where the final discussion and decision of the subject takes place. See *Réglement pour la Chambre des Députés*, Paris, 1827.

Burgundy Wines are produced in the former provinces of Upper and Lower Burgundy, in a soil of a light-black or red loam, mixed with the *débris* of the calcareous rock on which it reposes. In richness of flavour and perfume, and all the more delicate qualities of the juice of the grape, they are inferior to none in the world. It is to the great skill with which the cultivation of the vine and the fermentation of the liquor are managed, that they owe those generous qualities, which gave to the dukes of Burgundy the title of *princes des bon vins*, and which, as Petrarch more than hints, contributed not a little to prolong the stay of their holinesses at Avignon. They are remarkable for their spirituosity and powerful aroma, and are therefore more heating than some other wines which contain more alcohol. The exhilaration they produce is, however, more innocent than that resulting from heavier wines. The finer wines of Burgundy do not bear removal except in bottles; and as they are not produced in great abundance, they are rarely, if ever, met with in foreign countries. It is the inferior growths which are sold under that name. The Burgundy wines are generally exported between January and May, chiefly in double casks. They keep only four or five years, and are very apt to acquire a bitter taste, which Chaptal attributes to the developement of the acerb principle, and Henderson to that of citric ether. It may sometimes be partially removed by new sulphuring and fining. The most numerous are the red wines of Burgundy. The finest growths of these are the Romanée-Conty, the Chambertin (the favourite of Louis XIV. and Napoleon), the Closbougeot, the Rhichebourg, the Romanée de St. Vivant, &c. They are distinguished for their beautiful colour and ex-

quisite flavour and aroma, combining more than any other wines, lightness and delicacy, with richness and fulness of body. Of the second class are the *vins de primeur*, of which the Volnay and Pomard are the best; those of Beaune, distinguished above all by their pure flavour, and formerly considered the most choice of the Burgundy wines; the Macon wines, remarkable for their strength and durability; those of Tonnerre and Auxerre, &c. The white wines of Burgundy are less numerous, but not inferior in aroma and flavour. The famous Montrachet is equal to the finer red wines, and is distinguished for its agreeable nutty flavour. Of the second class are the *Goutte d'or*, so called from the splendour of its tint; La Perrière, &c. See Jullien's *Classification des Vins*, and Henderson's *Ancient and Modern Wines*.

Burin, or Graver; an instrument of tempered steel, used for engraving on copper. It is of a prismatic form, having one end attached to a short wooden handle, and the other ground off obliquely, so as to produce a sharp point. In working, the burin is held in the palm of the hand, and pushed forward so as to cut a portion of the copper. The expressions *brilliant* burin, *soft* burin, are used to characterize the manner of a master.

Burning-Glass; a lens which unites the rays of light that fall upon it in so narrow a space as to cause them to kindle any combustible matter coming in their way like fire. The same name has been sometimes given, though improperly, to the burning-mirror. The lenses commonly used as burning-glasses are convex on both sides; these bring the rays upon a point with the greatest force, because of the shortness of their focal distance. The effects of a burning-glass are more powerful in proportion as its surface is greater, and its focus smaller. That such a glass may produce its greatest effect, it is necessary that the rays of the sun should fall upon it in a perpendicular direction, which is the case when the image of the sun, that appears at the moment of burning, is circular. If a second lens, of a smaller focal distance, is placed between the first and its focus, so as to intercept the rays which pass through the first, they are still more condensed, and united in a still narrower compass, so that the effect is greatly augmented. The Greeks and Romans seem to have been acquainted with burning-glasses, or at least with a kind of transparent stones similar to them. They became more known in the 13th century. At the close of the 17th, von Tschirnhausen caused the largest burning-glasses, consisting of one piece, that are known, to be polished with incredible pains. Two of them, still in Paris, are 33 inches in diameter, and the weight of one amounts to 160 pounds. Both glasses produce an effect equal to that of the most intense fire. They kindle wood, which is both hard and wet in a moment, and make cold water, in small vessels, boil in an instant; metals placed upon a plate of china, are melted and vitrified by them; tiles, slates, and similar objects, become instantly red-hot and vitrified. As Tschirnhausen's glasses, however, are not perfectly clear, and the effect is thus considerably lessened, Brisson and Lavoisier undertook, in 1774, to put together two lenses, resembling those used for watch-glasses, filling up the space between them with a transparent fluid. In this manner, veins and impurities may be avoided at less expense. They succeeded in making a burning-glass of 4 feet in diameter, the greatest thickness of which, in the centre, amounted to 8 inches, and which of itself had a much greater power than the glasses of Tschirnhausen, in connection with a smaller lens, or collective glass, but produced an extraordinary effect if joined to a collective glass. The experiments made by means of large burning-glasses are important in chemistry and physics. The power of a burning-glass, however, is almost four times less than that of a burning-mirror or reflector, of equal extent and equal curvature. This reflects more light than the glass allows to pass through it; has a smaller focal distance, and is free from the dissipation of the rays which takes place in the burning-glass, since it reflects them all nearly to one point, while the burning-glass refracts them to different points. On the other hand, the burning-glass is much more convenient, on account of the place of its focus, which is behind the glass. The burning point (focus) is an image of the sun; its diameter is equal to the 108th part of the focal distance, and its centre is the *focus*, properly so called. In the higher branches of geometry and conic sections, the *foci* are points in the parabola, ellipsis, and hyperbola, where the rays reflected from all parts of these curves meet. Several accidents in modern times have shown that conflagrations may be caused by convex window-glasses or water-bottles, &c., which have the form of burning-glasses, if the rays of the sun are concentrated by them upon combustible substances lying within their reach. Since the casting and polishing of large lenses are attended with great difficulties, Sir David Brewster's plan of casting them in pieces, or zones, and afterwards putting them together, has lately been practised. Lenses of this last kind have been ingeniously applied, by Becquey, for augmenting the light on light-houses, according to the suggestion of Fresnel. (See Pharos.) For the history of burning instruments, see the article Burning-Mirrors.

Burning-Mirrors, or Reflectors; mirrors, the smoothly polished surface of which reflects the rays of the sun that fall upon it in such a direction, that they unite at some distance from the mirror, in a more limited space, and act upon substances within this space like the most powerful fire. Concave mirrors cause the rays that fall upon them in a direction parallel to their axes to converge. Spherical mirrors of this kind are the most common; but parabolic ones are also used; and even plane mirrors may be employed like concave ones, if several of them are combined in a proper manner. In order that a burning-mirror should produce its whole effect, its axis must be directed exactly towards the centre of the sun's disc. This is the case if the light, intercepted by a plane, perpendicular to the axis of the mirror, at its focal distance, forms a circle. The focus then lies in a straight line between the sun and the mirror. The ancients were acquainted with such mirrors, as is manifest from several of their writings still extant. It is impossible, from the nature of things, that Archimedes, during the siege of Syracuse by Marcellus, should have set on fire the fleet of the latter by means of concave mirrors: it would be more credible, that it had been effected by a combination of plane mirrors. Various experiments have shown that great effects may be produced, at a considerable distance, by the latter instrument. Kircher placed five plane mirrors, of an equal size, in such a

position as to reflect the rays upon a spot one hundred feet distant, and thereby produced a great heat. Buffon, in 1747, effected a combination of 168 plane mirrors, each of which was 6 inches broad, and 8 long. With forty of these mirrors, he set on fire almost instantaneously a board of beech wood, covered with tar, at a distance of 66 feet; and with 128 mirrors, a board of pine wood, likewise covered with tar, at a distance of 150 feet. With 45 mirrors, he melted a tin bottle at a distance of 20 feet, and with 117 mirrors, small pieces of money. He afterwards burned wood with this machine, at the distance of 200 feet, melted tin at the distance of 150, lead at the distance of 130, and silver at the distance of 60 feet. During the last century, several large mirrors were made in Italy, two of which are still in Paris and Cassel. Von Tschirnhausen also manufactured one in 1687, 3 Leipsic ells (about $5\frac{1}{2}$ English feet) in diameter, and the focal distance of which was 2 ells ($3\frac{7}{10}$ English feet.) It consists of a thin plate of copper, highly polished, and is now in the mathematical hall in Dresden. This mirror sets wood on fire, makes water boil, melts tin three inches thick, as well as lead, vitrifies bricks, bones, &c. Besides metals, wood, pasteboard, glass, and other materials, serve for burning-mirrors, if their surface be polished. Burning mirrors have of late been used as reflectors to throw light at a great distance, and may be very usefully employed in light-houses. If, for instance, a lamp is placed in the focus of a parabolic mirror, the rays of light which fall on it are all reflected in a direction parallel to the axis; thus the reflectors of Lenoir appear like stars of the first magnitude at the distance of 80,000 feet. (For farther information on burning-glasses and burning-mirrors, see Priestley's *History and Present State of Optics;* and the 5th vol. of the new edition of Gehler's *Physikalisches Lexicon*, Leips. 1825.)

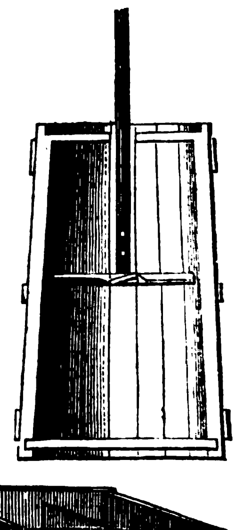
Burnisher is a blunt, smooth tool, used for smoothing and polishing a rough surface by pressure, and not by removing any part of the body. Other processes of polishing detach the little asperities. Agates, tempered steel, and dogs' teeth, are used for burnishing. It is one of the most expeditious methods of polishing, and one which gives the highest lustre. The burnishers used by engravers are formed to burnish with one end, and to erase blemishes with the other.

Bursa Mucosa, *in Anatomy*, is an apparatus for facilitating the motion of the muscles and tendons upon these parts.

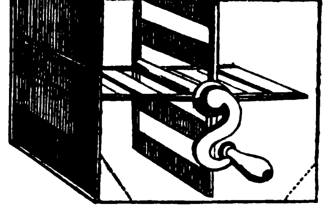
Bushel; an English dry measure, containing 8 gallons or 4 pecks. It is also used in the North American United States. The standard English bushel (12 Henry VII.) contained 8 gallons of wheat, each of 8 pounds troy, each of 12 ounces, each of 20 pennyweights, each of 32 corns of wheat that grew in the middle of the ear. In 1696, a duty being laid upon malt, it became necessary to ascertain the exact contents of the *Winchester bushel*, as that of Henry VII. was called. It was found that the capacity was 2151.7 cubic inches of pure water, equivalent to 1131 oz., 13 dwts. troy. (See J. Q. Adams's *Report upon Weights and Measures*, Washington, 1821.) The capacity of the *Imperial bushel*, prescribed by the act of uniformity (5 Geo. IV. c. 74), which took effect, January 1, 1826, is for coal, potatoes, fruits, and other goods sold by *heaped measure*, 2815 cubic inches, the goods to be heaped up in the form of a cone, to a height above the rim of the measure of at least three-fourths of its depth. The imperial bushel for all liquids, and for corn and other dry goods *not heaped*, contains 2218.20 cubic inches, and holds 80 lbs. avoirdupois of pure water.

Bust (Italian, *il busto*, from the Latin *bustum*), in *Sculpture;* the representation of that portion of the human figure which comprises the head and the upper part of the body. Busts are of different extent: 1. such as consist of the head, the upper part of the neck, and the upper part of the shoulders; 2. heads with the upper part of the chest, to the end of the breast-bone (*busts* properly so called); and 3. heads with the whole chest to the middle of the body, often to the hips. Between the bust and its pedestal is sometimes a column, or a square prop; such a bust is called *Herme*. The figure is sometimes in relief. The origin of the bust may be derived from the Herme, and from the custom of the Greeks and Romans to decorate their shields with portraits, and their vestibules with the images of their ancestors. Busts were afterwards used for the images of their gods, as being less expensive. The greater part have been found in Rome and Italy. Some remarkable ones have been obtained from Herculaneum in bronze. The chief difficulty in the execution of busts arises from this circumstance, that we are accustomed to estimate the size of the head by comparing it with the whole body. In a bust, therefore, the head appears disproportionately large, and the artist is obliged to yield, in some measure, to this ocular deception, by lessening its natural proportion.

Butter; an oily substance, produced from the milk of kine. *Cream* is composed of an oily substance, a caseous matter, and serum or whey. If it be agitated for a given period in a churn, a separation of these parts takes place, and a solid, called *butter*, and a liquid, called *butter-milk*, consisting of the whey, are the products.



The common butter churn is represented in the annexed engraving, consisting of a plunger or flat piston, put in motion in a perpendicular direction, which by agitating the cream, separates the butter from the thin fluid.



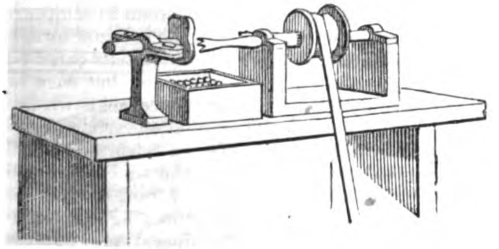
Turning from this primeval instrument, we come to a box machine with a series of plungers revolving in the opposite direction, which will usually separate the chemical constituents of the milk, and produce butter in less than half the time required by the former instrument.

The proportions of these products in butter, in 100 parts of cream, are,

Butter	4.5
Cheese	3.5
Whey	92.0
	100.0

Chemical analysis gives stearine, elaine, and a small quantity of acid and colouring matter, as the component parts of butter. Beckmann (*History of Inventions*, 372) comes to the conclusion that butter is not of Grecian nor of Roman invention; but that the Greeks received it from the Scythians, Thracians, and Phrygians, and that the Romans derived it from the people of Germany, and used it as a medicine, rather than as a culinary luxury. In warm countries, the place of butter is still, for the most part, supplied by oil. In Italy, Spain, Portugal, and the south of France, it is to be purchased in the apothecaries' shops. The difficulty of keeping it any length of time is, indeed, an effectual barrier to its general use. The ancients appear to have been wholly deficient in the art of giving it consistency. The European countries in which oil or butter is used, says Malte-Brun (*Géog.* liv. xcv.), may be separated by a line extending along the Pyrenees, the Cevennes, the Alps, and Mount Hæmus. To the north the pasturage is better; cattle abound, and the food is chiefly derived from them. The butter, beer, and animal food of the north of Europe, give way to oil, wine, and bread, in the warmer regions. The word *chameah*, translated *butter*, in the English version of the Bible, means some liquid preparation of milk or cream. It was in general use among the Celts:—*Spuma id est lactis, concretiorque quam quod* serum *vocatur, barbararum gentium lautissimus cibus*. (*Pliny*, ix. 41, and xxviii, 9). The Hindoos make use of *ghee*, which means butter clarified by boiling. They boil the milk two or three hours, which, when cool, is fermented with curdled milk, left to sour, churned, and when it is sufficiently rancid, is boiled and mixed with salt, or betel-leaf and ruddle, to improve its taste and colour.

Buttons are of almost all forms and materials—wood, horn, bone, ivory, steel, copper, silver, similor, &c. The tailor covers them with stuffs, and the female artisan envelopes them with a texture of thread, silk, cotton and gold or silver thread. The non-metallic buttons, called also *moulds*, are made of the substances first mentioned, by sawing them into little slips of the thickness of the button to be made.



The most curious part of button-making consists in the simple machine or lathe by which the material is cut into a round form. It is represented above, and consists of two thin knives on a pointed axis, the whole of which revolves, and thus cuts the circular disc. The holes are afterwards drilled in a similar lathe, provided with four axes turning from a wheel, which is put in motion by the foot of the workman.

Metallic buttons are cast in moulds, or cut by a fly-press. Any figure or inscription may be impressed on them at the same time that they are cut. The little wire ring by which they are attached to a garment, is called the *shank*, and is soldered separately on each button. The details of smoothing, polishing, boiling, &c., would occupy too much room. The face of the button is generally plated or gilt. Dr. Church, an American, obtained a patent in England (1829), for an improved manufacture of buttons with a metallic shank, the face being either of polished metal, or covered with any fabric. The various operations of shaping the discs, forming the shanks, cutting the cloth, and covering the faces of the buttons, are all effected by one revolving shaft.

Buttresses, in *Gothic Architecture*, are lateral projections on the outside of the walls of an edifice, extending from the top to the bottom, at the corners, and between the windows. They are necessary to support the walls, and prevent them from spreading under the weight of the roof.

Byzantine School of Art. After Constantine the Great had made the ancient Byzantium the capital of the Roman empire, and ornamented that city, which was called after him, with all the treasures of Grecian skill, a new period commenced in the history of art. From this time it became subservient to Christianity, as the religion of the state. All the productions of heathen artists which formed suitable ornaments for Christian cities and temples, were now employed in the service of the invisible God, and art began by slow degrees to rise from its degeneracy, under the influences of Christianity. At the time when Constantine converted Byzantium into an imperial residence, splendour and ornament had already supplanted the simplicity of ancient taste. Asiatic luxury had become predominant, and this laid more stress on richness of material and decoration than on purity of conception. Architecture which adorned the *forum Augusteum*, in Byzantium, with a fourfold colonnade, and created splendid *curiæ*, imperial palaces, baths, theatres, and porticoes, preserved for a long time the grand forms of classic times, and deviated from them slowly and gradually, at first in the Christian churches, as a model for which Justinian built the church of St. Sophia, and decorated it with Oriental magnificence, in 537. But even in architecture, the costliness and colour of the marble was soon considered as of more importance than the proportion of the parts and the distribution of the columns. There are, however, as late as the ninth century, admirable works of Greek architecture, particularly those of Theodosius the Great and Justinian. This period was still less favourable to the simplicity of sculpture. The mythology of ancient Greece afforded sacred subjects to the statuary. Gods appeared in the human form, and the human figure, in the Grecian model, was raised to the classical ideal. On the introduction of the Christian religion, sculpture was confined to the imitation of nature; afterwards to portraits, and to mere purposes of ornament; for Christianity is averse to sensible representations of the Divinity. Statues of emperors, of great statesmen and generals, became the subjects of the sculptor, and seem eventually to have given rise to the introduction of the worship of images in the Christian churches, since the custom of erecting mo-

numents and statues to the emperors and distinguished bishops, was extended to martyrs and saints, and was afterwards followed by the superstitious and impious worship of them. Though images of this kind became more frequent in the third and fourth centuries, there were yet many Christian teachers, who, like Tertullian, at an early period, declared the fine arts inventions of the devil, and the pagan statues possessed by demons. This superstition often caused the destruction of the noblest statues of the Grecian gods by popular violence. It was not until after many difficulties, that, in the ninth century, the worship of images was established in the Greek empire, and after that time appeared the first known traces of Christian sculpture and painting in the East. But even those statues to which sculpture was now confined, no longer displayed the freedom and dignity of ancient art. The pride of the emperors demanded statues of gold and silver, as long as their treasury, filled by exhausting their subjects, could supply them. Images of bronze and marble were despised. And how seldom could the artist be inspired by his subject, when flattery erected monuments and busts to the most worthless of men! It was natural, that, with the loss of elevated subjects, the dignity of art should be lost in petty technical details. Heyne, in his treatise on the later works of art, under the Byzantine emperors (*Commentat. Soc. Götting.*, vol. xi.), observes, that the representations of the emperors, of distinguished men, or of saints, were uniform in figure and character. The vestiges of genius were nowhere seen in free creations and ideal forms, in the desire of truth and expression. From the time of Justinian downwards, the true measure and proportion of the parts, and the correctness of the outlines were so much neglected, that the representations became constantly more like masks, spectres, and monsters. The old Roman faces were seldom represented: the forms appeared to belong to quite another race—to some new nation; and it was often necessary to write the names under them. In the perspective of the figures no rules were observed. It became at this time the great object to imitate the costly robes of the emperors, bishops, and other noble persons, who gratified their vanity not only with purple garments, but by the extravagant use of pearls and precious stones, which were worn in long pendants from the ear, in bracelets, and in necklaces. The whole mantle was often garnished with precious stones, and round the edge ran a double row of pearls. Such garments the emperor used to change several times a day. As such exterior ornaments are foreign from sculpture, which prefers the naked figure, or a simple drapery, it is easy to see why the production of statues ceased so soon. In the lists of Byzantine works of sculpture given by authors of the first centuries, there are no images of Christ, no statues of apostles and saints. Instead of them, we find only crucifixes, painted, or ornamented with mosaic work. If there were any such images in earlier times, they must have been destroyed in the time of the Iconoclasts, as was the case with the bronze statue of Christ, near that of Constantine, which was demolished by Leo, the general destroyer of images, and the representations of the *Good Shepherd*, praised by Eusebius, and that of *Daniel among the Lions*, with which Constantine adorned the public fountains. An image of the Saviour, surrounded by angels, and worked in mosaic, is described by Photius. We also find mention of the images of two angels upon the forum of Constantine, the representation of Adam and Eve, the bronze statue of Moses, with which Justinian is said to have ornamented the *curiæ*, and that of Solomon of an earlier date. According to Eusebius, the roof of the palace in Constantinople was also decorated with rich mosaics of gold and costly stones, representing scenes from the passion of Christ; and another, which Justinian erected, in Chalcis, contained representations of events in the war against the Vandals. The most celebrated of all the mosaics in the interior of St. Sophia's church in Constantinople has been preserved in fragments to modern times. The taste of those times inclined, in general, more to mosaic works than to sculpture; because the former were rendered attractive by the costliness and colours of the stones. Sculpture was employed particularly in ornamenting altars, tabernacles, holy vessels, and urns, which were made of the most precious marble. The art of engraving on stones was also long preserved. In the art of painting, which was imitated in mosaic, the taste of this age was the same as in sculpture—pleased with gold and lively colours, but careless about truth of representation, and beauty and grandeur of conception. The first germ of a Christian style of art was, however, developed in the Byzantine pictures. The ideal representations of human figures, which the ancient Grecian artists had exhibited in their master-works, were necessarily given up by Christian artists: another ideal was to be formed, which should not recall the odious features of paganism. But the ideal of the Saviour, of the mother of Christ, and of his apostles, could be formed only by degrees. The artists, who had nothing real and material before them, but were obliged to find, in their own imaginations, conceptions of the external appearance of sacred persons, could give but feeble sketches of their ideas by means of their imperfect art. In their representations of Jesus and his apostles, they finally adopted the national features of the Jews. In the figure, and sometimes even in the countenance, they imitated the external appearance of some revered bishop. The hands were often lifted, as in blessing, or one hand was laid upon the breast, or holding a book. Thus the figures of the founders of the Christian church were first represented in paintings. They were also exhibited in mosaic, but not in marble. Christian subjects, indeed, are generally more suited to painting, which gives the outward expression of the mind, by means of light and shade, and colours, than to sculpture, which, on the contrary, elevates the external form to a kind of spiritual dignity. As the artists cared but little for a faithful imitation of nature, but were satisfied with repeating what was once acknowledged as successful, it is not strange that certain forms, introduced by the authority of some celebrated artists, and approved by the taste of the time, should be made by convention, and without regard to truth and beauty, general models of the human figure, and be transmitted as such to succeeding times. In his treatise on the continuation of the arts in Constantinople (*Comment. Soc. Götting.* vol. xiii.), Heyne remarks, that art continued to be exercised here, as far as it consists in mechanical skill, in the use of instruments in particular rules and general precepts; but taste, and a sense for truth and simple beauty, had

vanished. Delicacy, elegance, and gracefulness in design, proportion of parts, harmony of the figures, and beauty of form were lost. The artists did not even aim at an accurate representation, but were contented with rude and general outlines, as may be seen in the coins of the time. These deformed and meagre figures were slavishly copied, and labour was lavished on costly, and often tasteless ornaments. A certain propensity to the grotesque prevailed, even in architecture. The influence of ancient works of art continually decreased as their number was diminished by the violences of war, by superstition, by avarice, and by the hand of time. Most of the then existing works of antiquity perished in the capture of Constantinople, during the crusades of 1204 and 1261; and thus the city had long been deprived of its most beautiful ornaments, when it was taken by the Turks, in 1453.—This was in general the state of art in the Byzantine empire. Its influence has been felt ever since; in earlier times, by the connection of the imperial residence in the East with the Western Empire, and afterwards by commercial intercourse and the crusades.—Let us first consider this connection of the lower Greek art with the west of Europe, and in particular with Italy. According to Stieglitz (on *German Architecture*), the character of the lower Greek architecture was tranquillity and simplicity, originating from poverty of ideas and materials, and terminating in heaviness. But this architecture, which prevailed till the earlier part of the middle ages, preserved the seed, from which in later times a new and better style sprung up. Constantinople became a school of architecture, from which artists issued to all parts of the Roman empire, as far as Britain, to erect churches after the model of St. Sophia. They also penetrated into the countries of the East, introducing their art among the Arabians, who applied it to the erection of their mosques, and among the Moors in Spain, who formed their own style from it. The lower Greek or Byzantine style kept itself pure and uncorrupted in Italy, under the Lombards, as well as under the Goths, whose artists came from the East; and thence it spread during the reign of Charlemagne, to Germany, Gaul, and England. The style of architecture introduced by Charlemagne into Germany, was a corruption of that prevailing in the lower Greek empire, from which, together with the Arabian and German style, sprang the true German or Gothic architecture, which flourished from the thirteenth to the sixteenth century. The *basso-relievos* which are found on the oldest churches in Germany, and some pictures in them, still show the traces of the lower Grecian art. There are also to be found in Gori (see *Diptych*, vol. 3, p. 33 and 270, tab. iv. and xxiii.) and Ciampini (*Vet. Moniment.*, part ii. p. 104, tab. xxix.), representations of Italian and Gallic sculpture, which, in their drapery, ornaments and architectural forms, betray a Byzantine origin.

In regard to painting, we are indebted to the Byzantines for the preservation of some portion of its ancient excellence. As, in the early period of Christianity, Grecian and Roman art, in general, differed but little, since both sprung from the ruins of ancient art, so, in painting, no striking difference is to be observed between them. They became, however, constantly more and more distinct, in later times, as Greece and Italy became more and more separated. Short, thick bodies, stiff and forced attitudes, exaggeration of the characteristic parts, in particular of the eyes, faces contracted above and broad below, and marked with overcharged tints, short thick hair, highly-arched eyebrows, awkward drapery, loaded with unnatural folds, distinguish the Greek pictures as far back as the fifth century. The better paintings, which are found particularly in manuscripts, show a neat, accurate, and diligent execution. When art declined in Italy, particularly in the ninth century, painting was still cultivated by the Greeks, who, driven from home by the disputes concerning images, carried it into Italy and other countries, and adorned the churches there. Thus the lower Greek or Byzantine school was the mother of the old Italian school, and of the lower Rhenish, which preceded the German. The relation of both is seen in the similarity of the Italian pictures to those of the lower Rhenish school. According to the common statement, several Grecian artists passed over into Italy, in the beginning of the 12th century, and adorned the churches of Florence and Venice with their works. These were joined by the Italian artists, who founded, in the thirteenth century, a school of art and painting (see ITALIAN ART), which in its developement acquired a peculiar character, distinguished by beauty both of conception and execution. The lower Rhenish school, however, which is also called the *school of Cologne*, as it flourished chiefly, from the beginning of the fourteenth to the beginning of the fifteenth centuries, in the city of Cologne, appears to have retained still more closely the Byzantine character than the Italian did, since there are traces of it even in the later German school, exhibited in the symmetrical and pyramidal grouping of the objects, in the close drapery, and in the love of ornament and splendour, shown particularly in the golden back-grounds. The collection of the brothers Boisserée contains the most excellent works of this school. John Van Eyck first set the example of a more individual representation of natural objects, in opposition to the general representations of the lower Greek, and the ideal style of the old Roman school. More exact accounts are wanting of the historical connection of the lower Rhenish and of the old Italian school with the Byzantine style of art. (For an history of the earlier times of the Byzantine school of art, see *Histoire de l'Art par les Monumens depuis sa Décadence au 14me Siecle, jusqu'à son Renouvellement au 16me;* Paris, 1810, folio.)

CABIN; an apartment in a ship for officers and passengers. In large ships there are several cabins, the principal of which is occupied by the commander. In small vessels, there is only one cabin, which is in the stern. The bed-places in ships are also called *cabins*, or, more commonly, *berths*. *Berth* is used, likewise, for the room where a number of men mess and reside.

CABINET; 1. a small apartment adjoining a larger one; 2. the most retired part of a private dwelling, designed for work, for amusement, or for collections of valuable articles. 3. In the abode of a prince, the cabinet is a room set apart for the ruler's particular use; also, the apartment where he transacts government business, advises with his privy counsellors, and issues his decrees. Hence, in political language, the cabinet is put for the government; as the cabinet of London, of Vienna, of the Tuileries, &c. 4. Finally, a cabinet is any part of a building, or one or more whole buildings, where are preserved valuable col-

lections from the kingdoms of nature or art; as paintings, plants, animals, coins, minerals, and curiosities of every description; and, by metonymy, the name is applied to the collections themselves. A work of art, and sometimes of nature, of uncommon beauty, and fitted from its size to be placed in a cabinet, is called a *cabinet-piece*. A *cabinet-painter* is one who executes small highly-finished pictures, suitable for cabinets.

Cable; 1. in architecture, wreathed circular mouldings, resembling a robe; also, the staff which is left in the lower part of the flutings of some examples of the Corinthian and Composite orders.—2. In naval affairs, it is a long, thick rope, formed of 3 strands of hemp, which is employed for confining a vessel to its place by means of an anchor or other fixed body. The long and heavy chains which have been recently introduced for this purpose, are also called *cables*. Large vessels have ready for service 3 cables—the *sheet* cable, the *best bower* cable, and the *small bower* cable. They should be at least 100 or 120 fathoms in length. A best bower cable, of 25 inches in circumference, is formed of 3240 threads. The invention of iron cables is of recent date, and they have supplanted those of hemp in ships of war. They are stronger, less liable to be destroyed on rocks, &c. It is sometimes desirable to cut the cable when of hemp: this contingency is provided for in iron cables by a bolt and shackle at short distances, so that, by striking out the bolt, the cable is easily detached.—*Cable's length* is used to signify the measure of 120 fathoms, the usual length of a cable.

Caboose; the cook-room or kitchen of a ship. In smaller vessels, it is an enclosed fireplace, hearth, or stove, for cooking, on the main deck. In a ship of war, the cook-room is called a *galley*.—Caboose also signifies the box that covers the chimney in a ship.

Cacao. Chocolate is a kind of cake, or hard paste, the basis of which is the pulp of the cacao, or chocolate-nut, a production of the West Indies and South America. The cacao-tree (*theobromo cacao*), both in size and shape, somewhat resembles a young cherry-tree, but separates, near the ground, into four or five stems. The leaves are about four inches in length, smooth, but not glossy, and of a dull green colour. The flowers are saffron-coloured, and very beautiful. The fruit of the cacao-tree somewhat resembles a cucumber in shape, but is furrowed deeper on the sides. Its colour, while growing, is green; but, as it ripens, this changes to a fine bluish-red, almost purple, with pink veins; or, in some of the varieties, to a delicate yellow or lemon colour. Each of the pods contains from 20 to 30 nuts or kernels, which, in shape, are not much unlike almonds, and consist of a white and sweet pulpy substance, enveloped in a parchment-like shell. These are the cacao or chocolate-nuts.—Plantations of cacao are numerous on the banks of the river Magdalena, in South America. They are usually formed in morassy situations, and are sheltered from the intense heat of the sun by larger trees, which are planted in them. There are two principal crops of cacao in the year; the first in June, and the second in December. As soon as the fruit is ripe, it is gathered, and cut into slices; and the nuts which are at this time, in a pulpy state, are taken out, and laid in skins, or on leaves to be dried. They have now a sweetish acid taste, and may be eaten like any other fruit. When perfectly dry, they are put into bags, each containing about a hundred weight, and, thus packed, are exported to foreign countries. Previously to being formed into chocolate, these nuts are generally toasted or parched over the fire in an iron vessel, after which process their thin external covering is easily separated. The kernel is then pounded in amortar, and subsequently ground on a smooth, warm stone. Sometimes a little arnatto is added; and, with the aid of water, the whole is formed into a paste. This is put, whilst hot, into tin moulds, where in a short time it congeals; and in this state it is the chocolate of the shops. In South America and Spain, other modes are adopted: the chocolate is mixed with sugar, long pepper, vanilla, cinnamon, cloves, almonds, and other ingredients, according to the taste of the respective inhabitants. Mr. Edwards was of opinion, that the cakes of chocolate consumed in England were made of about one half cacao, and the remainder of flour or castile soap. That from Caraccas is considered the best.—By the natives of South America, the chocolate nuts are used for food. A white, oily matter, about the consistence of suet, is also obtained by bruising them, and boiling the pulp. The oil is by this means liquified, and rises to the surface, where it is left to cool and congeal, that it may the more easily be separated. This, which is called *butter of cacao*, is without smell, and when fresh, has a very mild taste. Its principal use is as an ingredient in pomatums. From the nuts, when slightly roasted, an oil is sometimes obtained by pressure, which is occasionally used in medicine.

Cadence, or Reprise; a pause or suspension at the end of an air, to afford the performer an opportunity of introducing a graceful extempore close. The word *cadence* is also frequently applied to the embellishment itself.

Cæsarian Operation. See Midwifery.

Cahors Wine is that wine which is used to improve the Pontac and other red French wines. It is consumed in Bourdeaux and other places, where the lighter and cheaper French wines find a ready market.

Caisson; 1. a chest filled with combustibles, and buried under ground, in order to explode at a particular time. It is also a covered waggon for the provisions and ammunition of an army.—2. In architecture, a kind of chest, case, or flat-bottomed boat, used in the construction of bridges, large enough to contain an entire pier, which is built in it; the caisson is then sunk to the bed of the river, and the sides removed from the bottom, which is left as a foundation for the pier.—Floating vessels, under the same name, are used to close the entrances of docks and basins. A groove is worked in the masonry of the entrance, and a vessel of the shape of the opening, with a projection corresponding to the groove, a hanging scuttle on each side, and furnished with pumps, is floated into it at high tide. The scuttles being opened, the caisson sinks, and fills up the groove. The scuttles are then shut, and the water is prevented from entering the dock, or from discharging itself from the basin. If the dock is to be filled, the scuttles are opened, till the water is nearly on a level on each side, when the scuttles are again shut, the caisson emptied by the pumps, and then floated off.

Cajeput Oil; the volatile oil obtained from the leaves of the cajeput-tree—the *cajeputa officinarum* (the *melaleuca leucadendron* of Linnæus). The tree which furnishes the cajeput oil is common on the mountains of Amboyna, and the other Molucca is-

lands. It is obtained by distillation from the dried leaves of the smaller of two varieties. It is prepared in great quantities in the island of Banda, and sent to Holland in copper flasks. As it comes to us, it is of a green colour, very limpid, lighter than water, of a strong smell resembling camphor, and of a strong, pungent taste. It burns entirely away, without leaving any residuum. It is often adulterated with other essential oils, coloured with the resin of milfoil. In the genuine oil, the green colour depends on the presence of copper; for when rectified it is colourless.

CALAMANCO; a woollen stuff, principally manufactured in the Netherlands. The English manufactures of it have declined of late years. The warp is sometimes mixed with silk or goats' hair. This stuff is made plain, coloured, striped, or watered.

CALAMATA. See GREECE.

CALAMINE. See ZINC.

CALCARIOUS SPA; a combination of lime and carbonic acid. See LIME.

CALCINATION. Calcination, as commonly understood, consists in heating bodies in a steady fire, at a greater or less temperature. The product is a powder which is called *calx*. In a narrow sense, we understand by this process a change of metals into a metallic calx, or metallic earth. Metals are calcined in two ways—by the dry method, which consists in burning them in the open air, or by the wet method, which consists in dissolving the metal and precipitating its calx. Take, for instance, a quantity of lead, and melt it in the open air in a flat vessel; it soon assumes a grayish hue, the earthy substance forming a coat on the surface. Upon the removal of this, the metal appears having a brilliant lustre, and after some time, the same gray coat reappears. It may be removed as long as any lead remains. This substance is the calx. Calcined lead is specifically lighter than the metal, but its absolute weight is considered greater, so that 10 pounds of metal makes 11 pounds of calx. Platina, gold, and silver are not affected in this way in so great a degree, on which account they are called the *perfect metals*. Chemists are now convinced, that in this process the atmospheric air is decomposed, and a portion absorbed by the metal, which accounts for its increase of weight. Calcination is, therefore, nothing but oxydation; and, as the body is not saturated with oxygen, no acid is formed, but the result is a metallic oxide.

CALCOGRAPHY. See ENGRAVING.
